This method has been shown to be applicable to medium rings (10–14 members) without the use of high-dilution techniques.[1600]

The mechanism of these reactions is usually S_N2 with inversion taking place at a chiral RX, although an SET[1601] mechanism may be involved in certain cases,[1602] especially where the nucleophile is an α-nitro carbanion[1603] and/or the substrate contains a nitro or cyano[1604] group. Tertiary alkyl groups can be introduced by an S_N1 mechanism if the ZCH_2Z' compound (not the enolate anion) is treated with a tertiary carbocation generated *in situ* from an alcohol or alkyl halide and BF_3 or $AlCl_3$,[1605] or with a tertiary alkyl perchlorate.[1606]

Alkylation α to a nitro group can be achieved with the Katritzky pyrylium–pyridinium reagents.[1607] This reaction probably has a free-radical mechanism.[1608]

CN is in the range of 19–25 (see p. 363), and a base that has a conjugate acid with a pK_a greater than that proton must be employed. Note that since only one activating group is present here, compared with two activating groups for the substrates in **10-67**, the pK_a of the α-proton is higher (a weaker acid) and a stronger base is required. Reaction of the α-proton with the base generates they key nucleophilic intermediate, an enolate anion (**159**). The most common bases[1612] are lithium diethylamide (Et_2NLi), lithium diisopropylamide[(iPr)$_2$NLi, LDA], *t*-BuOK, $NaNH_2$, and KH. A combination of lithium hexamethyldisilazide [$LiN(SiMe_3)_2$] followed by $MnBr_2$ is also effective for alkylation of ketones.[1613] The base lithium *N*-isopropyl-*N*-cyclohexylamide (LICA) is particularly successful for carboxylic esters[1614] and nitriles.[1615] Solid KOH in Me_2SO has been used to methylate ketones, in high yields.[1616] Some of these bases are strong enough to convert the ketone, nitrile, or ester completely to its enolate anion conjugate base; others (especially *t*-BuOK) convert a significant fraction of the molecules. In the latter case, the aldol reaction (**16-34**) or Claisen condensation (**16-85**) may be side reactions, since both the free molecule and its conjugate base are present at the same time. It is therefore important to use a base strong enough to convert the starting compound completely. Both lactones[1617] and lactams are similarly alkylated.[1618] Protic solvents are generally not suitable because they protonate the base (though of course this is not a problem with a conjugate pair, such as *t*-BuOK in *t*-BuOH). Some common solvents are 1,2-dimethoxyethane, THF, DMF, and liquid NH_3. Phase-transfer catalysis has been used to alkylate many nitriles, as well as some esters and ketones.[1619]

Direct alkylation of aldehydes is difficult when bases, such as KOH and NaOMe, are used due to rapid aldol reaction (**16-34**), but aldehydes bearing only one α hydrogen have been alkylated with allylic and benzylic halides in good yields by the use of the base KH to prepare the potassium enolate,[1620] or in moderate yields, by the use of a phase-transfer catalyst.[1621] Even the use of amide bases such as

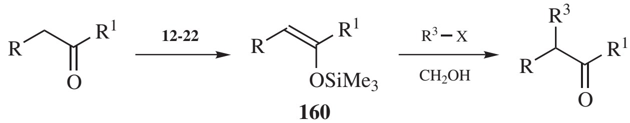
lithium diisopropylamide (LDA), lithium hexamethyldisilazide (LHMDS), or lithium tetramethylpiperidide (LTMP) to generate the enolate anion in an aprotic solvent, such as ether or THF, cannot preclude rapid aldol side reactions.

As in **10-67**, the alkyl halide that reacts with the enolate anion may be primary or secondary. Tertiary halides give elimination. Even primary and secondary halides give predominant elimination if the enolate anion is a strong enough base (e.g., the enolate anion from Me_3CCOMe).[1622] Tertiary alkyl groups, as well as other groups that normally give S_N1 reactions, can be introduced if the reaction is performed on a silyl enol ether[1623] of a ketone, aldehyde, or ester (see **160**) with a Lewis acid catalyst.[1624] Tertiary alkyl fluorides were coupled to silyl enol ethers with BF_3•etherate.[1625] An interesting reaction reacted a methyl ketone, such as acetophenone (1-phenyl-1-ethanone) with tributylamine, in the presence of a ruthenium catalyst at 180°C, and the product resulted from *C*-alkylation (1-phenyl-1-hexanone).[1626] Note that tin enolates (C=C—OSnR$_3$) react with halides in the presence of a zinc catalyst.[1627] A chiral variation of this latter reaction was reported involving generation of the enolate anion in the presence of Me_3SnCl, a palladium catalyst and a chiral ligand.[1628]



160

Silyl enol ethers can be converted to the enolate anion, which can then be alkylated in the usual manner. The reaction of silyl enol ether **161** using KOEt followed by LiBr at a catalytic amount of *n*-butyllithium with allyl iodide gave **162**.[1629] Initial conversion of the silyl enol ether to the enolate anion allows the alkylation process to take place.

Enol carbonates react with alkylating agents in the presence of a palladium catalyst. The decarboxylative alkylation of allyl enol carbonates to the corresponding allylcyclohexanone derivatives is known as the *Tsuji alkylation.*[1630] An asymmetric version of this reaction has been reported.[1631] The same reaction can be done using enolate anion and allylic acetates with a palladium catalyst.[1632]

Vinylic and aryl halides can be used to vinylate or arylate carboxylic esters (but not ketones) by the use of $NiBr_2$ as a catalyst.[1633] Ketones have been vinylated by treating their enol acetates with vinylic bromides in the presence of a Pd compound catalyst,[1634] but direct reaction of a ketone, a vinyl halide, sodium *tert*-butoxide and a palladium catalyst also give the α-vinyl ketone.[1635] Also as in **10-67**, this reaction can be used to close rings.[1636] Rings have been closed by treating a dianion of a dialkyl succinate with a 1,ω-dihalide or ditosylate.[1637] This was applied to the synthesis of three-, four-, five-, and six-membered rings. When the attached groups were chiral (e.g., menthyl) the product was formed with >90% ee.[1636]

Efficient enantioselective alkylations are known.[1638] In another method enantioselective alkylation can be achieved by using a chiral base to form the enolate.[1639] Alternatively, a chiral auxiliary can be attached. Many auxiliaries are based on the use of chiral amides[1640] or esters.[1641] Subsequent formation of the enolate anion allows alkylation to proceed with high enantioselectivity. A subsequent step is

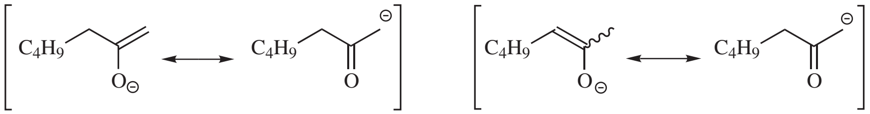
required to convert the chiral amide or ester to the corresponding carboxylic acid. Chiral additives can also be used.[1642]

When the compound to be alkylated is an unsymmetrical ketone, the question arises as to which side will be alkylated. If a phenyl or a vinylic group is present on one side, alkylation goes predominantly on that side. When only alkyl groups are present, the reaction is generally not regioselective; mixtures are obtained in which sometimes the more alkylated and sometimes the less alkylated side is predominantly alkylated. Which product is found in higher yield depends on the nature of the substrate, the base,[1643] the cation, and the solvent. In any case, di- and trisubstitution are frequent[1644] and it is often difficult to stop with the introduction of just one alkyl group.[1645]

Several methods have been developed for ensuring that alkylation takes place regioselectively on the *desired* side of a ketone.[1646] Among these are

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the other side; the blocking group is then removed. A common reaction for this purpose is formylation with ethyl formate (**16-86**); this generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (**12-43**).
2. Introduce an activating group on one side; alkylation then takes place on that side (**10-67**); the activating group is then removed.
3. Prepare the desired one of the two possible enolate anions.[1647] The two ions, for example, **163** and **164** for 2-heptanone, interconvert rapidly only in



163 **164**

the presence of the parent ketone or any stronger acid.[1648] In the absence of such acids, it is possible to prepare either **163** or **164** and thus achieve

[1642]Denmark, S.E.; Stavenger, R.A. *Acc. Chem. Res.* ***2000***, *33*, 432; Machajewski, T.D.; Wong, C.-H. *Angew. Chem. Int. Ed.* ***2000***, *39*, 1352.

[1643]Sterically hindered bases may greatly favor one enolate over the other. See, for example, Prieto, J.A.; Suarez, J.; Larson, G.L. *Synth. Commun.* ***1988***, *18*, 253; Gaudemar, M.; Bellassoued, M. *Tetrahedron Lett.* ***1989***, *30*, 2779.

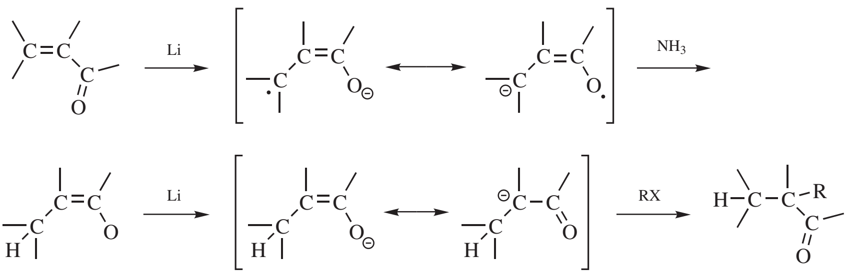
selective alkylation on either side of the ketone.[1649] The desired enolate anion can be obtained by treatment of the corresponding enol acetate with two equivalents of methyllithium in 1,2-dimethoxyethane. Each enol acetate gives the corresponding enolate, for example,

The enol acetates, in turn, can be prepared by treatment of the parent ketone with an appropriate reagent.[1241] Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable.[1648] An alternate procedure involves conversion of a silyl enol ether[1650] (see **12-17**) or a dialkylboron enol ether[1651] (an enol borinate, see p. 645) to the corresponding enolate anion. If the less hindered enolate anion is desired (e.g., **126**), it can be prepared directly from the ketone by treatment with LDA in THF or 1,2-dimethoxyethane (DME) at −78°C.[1652]

4. Begin not with the ketone itself, but with an α,β-unsaturated ketone in which the double bond is present on the side where alkylation is desired. Upon treatment with lithium in liquid NH_3, such a ketone is reduced to an enolate anion. When the alkyl halide is added, it must react with the enolate anion on



the side where the double bond was.[1653] Of course, this method is not actually an alkylation of the ketone, but of the α,β-unsaturated ketone, although the

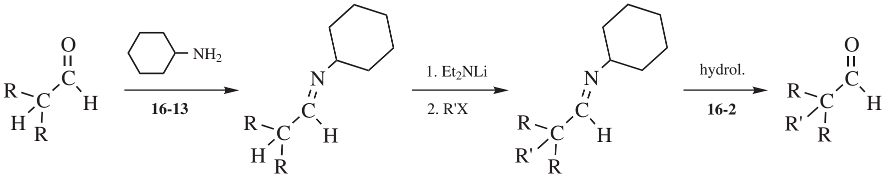
product is the same as if the saturated ketone had been alkylated on the desired side.

Both sides of acetone have been alkylated with different alkyl groups, in one operation, by treatment of the *N,N*-dimethylhydrazone of acetone with *n*-BuLi, followed by a primary alkyl, benzylic, or allylic bromide or iodide; then another mole of *n*-BuLi, a second halide, and finally hydrolysis of the hydrazone.[1654] Alkylation of an unsymmetrical ketone at the more substituted position was reported using an alkyl bromide, NaOH, and a calix[*n*]arene catalyst (see p. 122 for calixarenes).[1655]

Among other methods for the preparation of alkylated ketones are (*1*) Alkylation of silyl enol ethers using various reagents as noted above, (*2*) the Stork enamine reaction (**10-69**), (*3*) the acetoacetic ester synthesis (**10-67**), (*4*) alkylation of β-keto sulfones or sulfoxides (**10-67**), (*5*) acylation of $CH_3SOCH_2^-$ followed by reductive cleavage (**16-86**), (*6*) treatment of α-halo ketones with lithium dialkylcopper reagents (**10-57**), and (*7*) treatment of α-halo ketones with trialkylboranes (**10-73**).

Aldehydes can be indirectly alkylated via an imine derivative of the aldehyde.[1656] The derivative is easily prepared (**16-13**) and the product easily hydrolyzed to the aldehyde (**16-2**). Either or both R groups may be hydrogen, so that



mono-, di-, and trisubstituted acetaldehydes can be prepared by this method. R′ may be primary alkyl, allylic, or benzylic. Imine alkylation can also be applied to the preparation of substituted amine derivatives. An amino acid surrogate, such as $Ph_2C{=}NCH_2CO_2R$, when treated with KOH and an alkyl halide gives the *C*-alkylated product.[1657] When a chiral additive is used, good enantioselectivity was observed. This reaction has also been done in the ionic liquid bmim tetrafluoroborate (see p. 415).[1658] It is possible to alkylate α-amino amides directly.[1659]

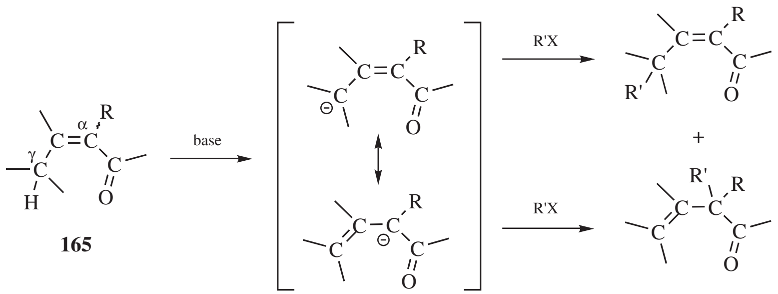
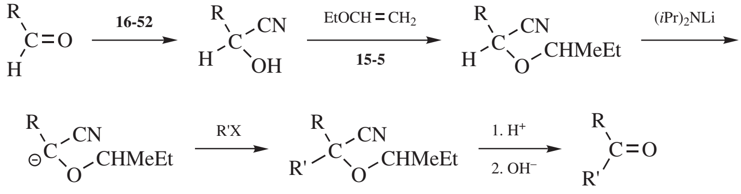
Hydrazones and other compounds with C=N bonds can be similarly alkylated.[1639] The use of chiral amines or hydrazines[1660] (followed by hydrolysis **16-2** of the alkylated imine) can lead to chiral alkylated ketones in high optical yields[1661] (for an example, see p. 170).



165

In α,β-unsaturated ketones, nitriles, and esters (e.g., **165**), the γ hydrogen assumes the acidity normally held by the position α to the carbonyl group, especially when R is not hydrogen and so cannot compete. This principle, called *vinylogy*, operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the α position (with allylic rearrangement) competes with alkylation at the γ position and usually predominates.



166

α-Hydroxynitriles (cyanohydrins), protected by conversion to acetals with ethyl vinyl ether (**15-5**), can be easily alkylated with primary or secondary alkyl or allylic halides.[1662] The R group can be aryl or a saturated or unsaturated alkyl. Since the cyanohydrins[1663] are easily formed from aldehydes (**16-52**) and the product is easily hydrolyzed to a ketone, this is a method for converting an aldehyde

RCHO to a ketone RCOR′[1664] (for other methods, see **10-71**, **16-82**, and **18-9**).[1665] In this procedure the normal mode of reaction of a carbonyl carbon is reversed. The C atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the protected cyanohydrin this carbon atom has been induced to perform as a nucleophile.[1666] The German word *Umpolung*[1667] is used to describe this kind of reversal (another example is found in **10-71**). Since the ion **166** serves as a substitute for the unavailable R—$^{\ominus}$ C=O anion, it is often called a "masked" R($^{\ominus}$C=O) ion. This method fails for formaldehyde (R = H), but other masked formaldehydes have proved successful.[1668] In an interesting variation of nitrile alkylation, a quaternary bromide [PhC(Br)(Me)CN] reacted with allyl bromide, in the presence of a Grignard reagent, to give the alkylated product [PhC(CN)(Me)$CH_2CH{=}CH_2$].[1669]

A coupling react of two ketones to form a 1,4-diketone has been reported, using $ZnCl_2/Et_2NH$.[1670]

[1671]This is the IUPAC name with respect to the halide as substrate.

When enamines are treated with alkyl halides, an alkylation occurs to give an iminium salt via electron transfer from the electron pair on nitrogen, through the C=C to the electrophilic carbon of the alkyl halide.[1672] In effect, an enamine behaves as a "nitrogen enolate" and generally react as carbon nucleophiles.[1673] Hydrolysis of the iminium salt gives a ketone. Since the enamine is normally formed from a ketone (**16-13**), the net result is alkylation of the ketone at the α position. The method, known as the *Stork enamine reaction*,[1674] is an alternative to the ketone alkylation considered in **10-68**, generally giving monoalkylation of the ketone. Alkylation usually takes place on the less substituted side of the original ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine.

The method is quite useful for particularly active alkyl halides, such as allylic, benzylic, and propargylic halides, and for α-halo ethers and esters. Other primary and secondary halides can show sluggish reactivity. The react of enamines with benzotriazole derivatives has been reported.[1675] Tertiary halides do not give the reaction at all since, with respect to the halide, this is nucleophilic substitution and elimination predominates. The reaction can also be applied to activated aryl halides (e.g., 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,[1676] and to activated alkenes, such as acrylonitrile. The latter is a Michael-type reaction (**15–24**) with respect to the alkene.

Acylation[1677] can be accomplished with acyl halides or with anhydrides. Hydrolysis of the resulting iminium salt leads to a 1,3-diketone. A COOEt group can be introduced by treatment of the enamine with ethyl chloroformate ClCOOEt,[1678] a CN group with cyanogen chloride[1679] (not cyanogen bromide or iodide, which leads to halogenation of the enamine), a CHO group with the mixed anhydride of formic and acetic acids[1678] or with DMF and phosgene,[1680] and a C(R)=NR′ group with a nitrilium salt $RC{\equiv}N^{+}R'$.[1681] The acylation of the enamine can take

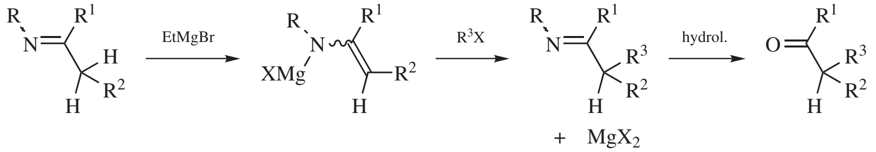
place by the same mechanism as alkylation, but another mechanism is also possible, if the acyl halide has an a hydrogen and if a tertiary amine is present, as it often is (it is added to neutralize the HX given off). In this mechanism, the acyl halide is dehydrohalogenated by the tertiary amine, producing a ketene (**17-14**), which adds to the enamine to give a cyclobutanone (**15-63**). This compound can be cleaved in the solution to form the same acylated imine salt (that would form by the more direct mechanism, or it can be isolated (in the case of enamines derived from aldehydes), or it may cleave in other ways.[1682]

N-Alkylation can be a problem, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF:[1683]



The imines are prepared by the reaction of secondary amines with aldehydes or ketones, mainly ketones (**16-13**). The enamine salt method has also been used to give good yields of mono α alkylation of α,β-unsaturated ketones.[1684] Enamines prepared from aldehydes and butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.[1685] *N*-Alkylation in this case is presumably prevented by steric hindrance.

When the nitrogen of the substrate contains a chiral R group, both the Stork enamine synthesis and the enamine salt method can be used to perform enantioselective syntheses.[1686] The use of *S*-proline can generate a chiral enamine *in situ*, thus allowing alkylation to occur, giving alkylated product with good enantioselectivity,. The reaction has been done intramolecularly.[1687]

Conjugate addition (Michael addition) occurs when enamines react with conjugated ketones. This reaction is discussed in Section **15-24**.

Although not formally the enamine synthesis, reaction of an enamine with methyl bromoacetate in the presence of indium metal leads to α-alkylation: $R_2N{-}CH{=}CHR \rightarrow R_2N{-}CH(R')CHR$.[1688]

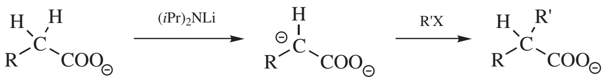
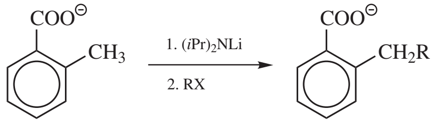
10-70 Alkylation of Carboxylic Acid Salts

α-Carboxyalkyl-de-halogenation



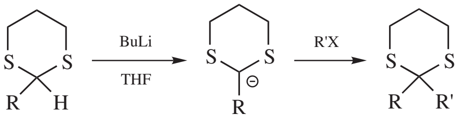
Carboxylic acids can be alkylated in the a position by conversion of their salts to dianions [which have resonance contributors $RCH{=}C(O^-)_2$[1689]] by treatment with a strong base, such as LDA.[1690] The use of Li^+ as the counterion increases the solubility of the dianionic salt. The reaction has been applied[1691] to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form RCH_2COOH and $RR^2CHCOOH$.[1610] Allkylation occurs at carbon, the more nucleophilic site relative to the carboxylate oxygen anion (see p. 513). this procedure is an alternative to the malonic ester synthesis (**10-67**) as a means of preparing carboxylic acids and has the advantage that acids of the form $RR'R^2CCOOH$ can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure.[1692]



OS **V**, 526; **VI**, 517; **VII**, 249. See also, OS **VII**, 164.

10-71 Alkylation at a Position α to a Heteroatom.

2-(2-Alkyl-thio)de-halogenation



The presence of a sulfur atom on a carbon enhances the acidity of a proton on that carbon, and in dithioacetals and dithioketals that proton ($RSCH_2SR$) is even more acidic. 1,3-Dithianes can be alkylated[1693] if a proton is first removed by

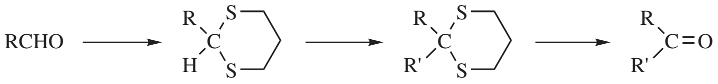
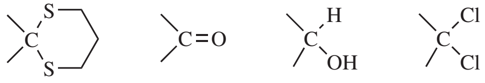
treatment with butyllithium in THF.[1694] Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS **VI**, 556) with 1,3-propanedithiol (**16-11**) and can be hydrolyzed (**10-7**), this is a method for the conversion of an aldehyde to a ketone[1695] (see also, **10-68** and **18-9**):



This is another example of Umpolung (see **10-68**);[1664] the normally electrophilic carbon of the aldehyde is made to behave as a nucleophile. The reaction can be applied to the unsubstituted dithiane (R = H) and one or two alkyl groups can be introduced, so a wide variety of aldehydes and ketones can be made starting with formaldehyde.[1696] The R′ group may be primary or secondary alkyl or benzylic. Iodides give the best results. The reaction has been used to close rings.[1697] A similar synthesis of aldehydes can be performed starting with ethyl ethylthiomethyl sulfoxide ($EtSOCH_2SEt$).[1698]



A **B** **C** **D**

The group **A** may be regarded as a structural equivalent for the carbonyl group **B**, since introduction of **A** into a molecule is actually an indirect means of introducing **B**. It is convenient to have a word for units within molecules; such a word is *synthon*, introduced by Corey,[1699] which is defined as a structural unit within a molecule that can be formed and/or assembled by known or conceivable synthetic operations. There are many other synthons equivalent to **A** and **B**, for example, **C** (by reactions **19-36** and **19-3**) and **D** (by reactions **10-2** and **16-23**).[1700]

Carbanions generated from 1,3-dithianes also react with epoxides[1701] to give the expected products.

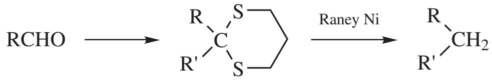
Another useful application of this reaction stems from the fact that dithianes can be desulfurated with Raney nickel (**14-27**). Aldehydes can therefore be converted to chain-extended hydrocarbons:[1702]



Similar reactions have been carried out with other thioacetals, as well as with compounds containing three thioether groups on a carbon.[1703]

If a stabilizing group other than sulfur is attached to the S-CH_2 unit of a thioether ($RSCH_2X$, where X is a stabilizing group), formation of the anion and alkylation can be facile. For example, benzylic and allylic thioethers ($RSCH_2Ar$ and $RSCH_2CH{=}CH_2$)[1704] and thioethers of the form $RSCH_3$ (R = tetrahydrofuranyl or 2-tetrahydropyranyl)[1705] have been successfully alkylated at the carbon adjacent to the sulfur atom.[1706] Stabilization by one thioether group has also been used in a method for the homologation of primary halides.[1707] Thioanisole is treated with BuLi to give the corresponding anion,[1708] which reacts with the halide to give the thioether, which is then refluxed with a mixture of methyl iodide and sodium iodide in DMF to give the alkyl iodide as the final product (via an intermediate sulfonium salt). By this sequence an alkyl halide RX is converted to its homolog RCH_2X by a pathway involving two laboratory steps (see also, **10-64**).

Vinylic sulfides containing an a hydrogen can also be alkylated[1709] by alkyl halides or epoxides. This is a method for converting an alkyl halide RX to an α,β-unsaturated aldehyde, which is the synthetic equivalent of the unknown $H^{\ominus}C{=}CH{-}CHO$ ion.[1710] Even simple alkyl aryl sulfides (RCH_2SAr and RR′CHSAr) have been alkylated to the sulfur.[1711]

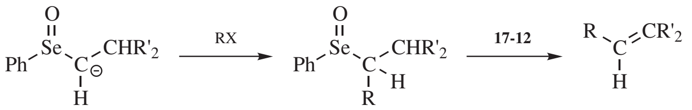
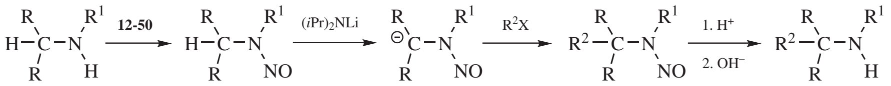
Sulfones[1712] and sulfonic esters can also be alkylated in the a position if strong enough bases are used.[1713] Alkylation at the α position of selenoxides allows the formation of alkenes, since selenoxides easily undergo elimination (**17-12**).[1714]



Alkylation can also be carried out, in certain compounds, at positions α to other heteroatoms,[1715] for example, at a position α to the nitrogen of tertiary amines.[1716] Alkylation α to the nitrogen of primary or secondary amines is not generally feasible because an NH hydrogen is usually more acidic than a CH



hydrogen. α-Lithiation of *N*-Boc amines has been accomplished and these react with halides in the presence of a palladium catalyst.[1717] Alkylation α to the nitrogen atom of a carbamate occurs when the carbamate is treated with a Grignard reagent under electrolysis conditions.[1718] α-Methoxy amides also react with allyl halides and zinc metal to give alkylation via replacement of the OMe unit.[1719] It has been accomplished, however, by replacing the NH hydrogens with other (removable) groups.[1720] In one example, a secondary amine is converted to its *N*-nitroso derivative (**12-50**).[1721] The *N*-nitroso product is easily hydrolyzed to the product

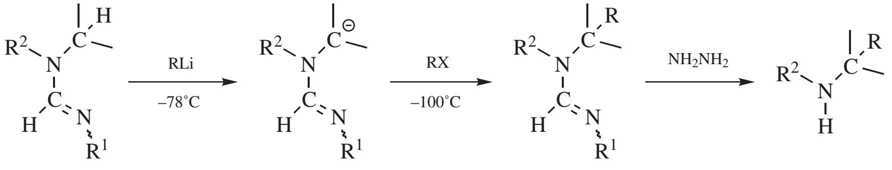
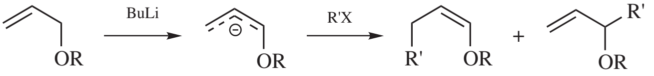
amine (**19-51**).[1722] Alkylation of secondary and primary amines has also been accomplished with >10 other protecting groups, involving conversion of amines to amides, carbamates,[1723] formamidines,[1724] and phosphoramides.[1719] In the case of formamidines (**167**), use of a chiral R′ leads to a chiral amine, in high ee, even when R is not chiral.[1725]



167

A proton can be removed from an allylic ether by treatment with an alkyllithium at about −70°C (at higher temperatures the Wittig rearrangement, **18-22**, takes place) to give the ion **168**, which reacts with alkyl halides to give the two products



168

shown.[1726] Similar reactions[1727] have been reported for allylic[1728] and vinylic tertiary amines. In the latter case, enamines **169**, treated with a strong base, are converted to anions that are then alkylated, generally at C-3.[1729] (For direct alkylation of enamines at C-2, see **10-69**.)

It is also possible to alkylate a methyl, ethyl, or other primary group of an aryl ester ArCOOR, where Ar is a 2,4,6-trialkylphenyl group.[1730] Since esters can be hydrolyzed to alcohols, this constitutes an indirect alkylation of primary alcohols. Methanol has also been alkylated by converting it to $^{\ominus}CH_2O^{\ominus}$.[1731]

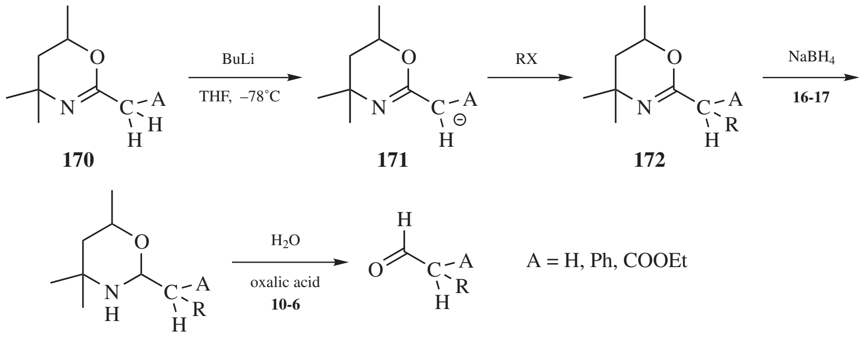
10-72 Alkylation of Dihydro-1,3-Oxazine: The Meyers Synthesis of Aldehydes, Ketones, and Carboxylic Acids



A synthesis of aldehydes[1732] developed by Meyers[1733] begins with the commercially available dihydro-1,3-oxazine derivatives **170** (A = H, Ph, or COOEt).[1734] Removal of a proton from the indicated carbon in **170** leads to the resonance stabilized and bidentate anion **172**. Alkylation occurs regioselectively at carbon by a many alkyl bromides and iodides. The R group of RX can be primary or secondary alkyl, allylic, or benzylic and can carry another halogen or a CN group.[1735] The alkylated oxazine **173** is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements **10-71**, which converts RX to an aldehyde containing one more carbon. Since A can be H, mono- or disubstituted acetaldehydes can be produced by this method.

The ion **171** also reacts with epoxides, to form γ-hydroxy aldehydes after reduction and hydrolysis,[1736] and with aldehydes and ketones (**16-38**). Similar aldehyde

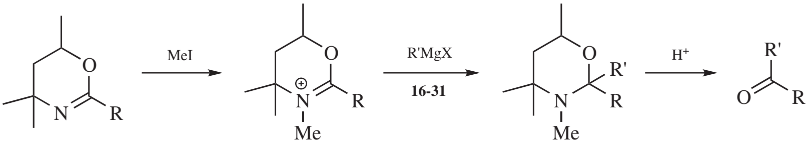
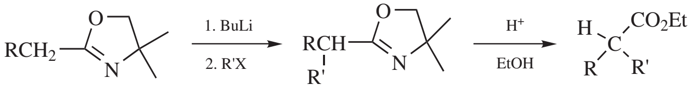
synthesis has also been carried out with thiazoles[1737] and thiazolines[1738] (five-membered rings containing N and S in the 1 and 3 positions).

The reaction has been extended to the preparation of ketones:[1739] Treatment of a dihydro-1,3-oxazine (**172**) with iodomethane forms the iminium salt **173** (**10-31**) which, when treated with a Grignard reagent or organolithium compound (**16-31**)



173 **174**

produces **174**, which can be hydrolyzed to a ketone. The R group can be alkyl, cycloalkyl, aryl, benzylic, and so on, and R′ of the Grignard reagent can be alkyl, aryl, benzylic, or allylic. Note that the hetereocycles **170**, **172**, or **173** do not react directly with Grignard reagents. In another procedure, 2-oxazolines (**175**)[1740] can be alkylated to give **176**,[1741] which are easily converted directly to the esters **177** by heating in 5–7% ethanolic sulfuric acid.



175 **176** **177**

2-Oxazolines **175** and **176** are thus synthons for carboxylic acids; this is another indirect method for the α alkylation of a carboxylic acid,[1742] representing an alternative to the malonic ester synthesis (**10-67**) and to **10-70** and **10-73**. The method can be adapted to the preparation of optically active carboxylic acids by the use of a chiral reagent.[1743] Note that, unlike **170**, **175** can be alkylated even if R is alkyl. However, the C=N bond of **175** and **176** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.[1744]

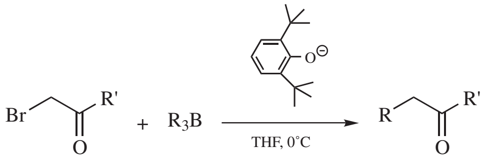
10-73 Alkylation with Trialkylboranes

Alkyl-de-halogenation



Trialkylboranes react rapidly and in high yields with α-halo ketones,[1745] α-halo esters,[1746] α-halo nitriles,[1747] and α-halo sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)[1748] in the presence of a base to give, respectively, alkylated ketones, esters, nitriles, and sulfonyl derivatives.[1749] Potassium *tert*-butoxide is often a suitable base, but potassium 2,6-di-*tert*-butylphenoxide at 0°C in THF gives better results in most cases, possibly because the large bulk of the two *tert*-butyl groups prevents the base from coordinating with the R_3B.[1750] The trialkylboranes are prepared by treatment of 3 equivalents of an alkene with 1 equivalent of BH_3 (**15-16**).[1751] With appropriate boranes, the R group transferred to α-halo ketones, nitriles, and esters can be vinylic,[1752] or (for α-halo ketones and esters) aryl.[1753]

The reaction can be extended to α,α-dihalo esters[1754] and α,α-dihalo nitriles.[1755] It is possible to replace just one halogen or both. In the latter case the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R. Another extension is the reaction of boranes (BR_3) with γ-halo-α,β-unsaturated esters.[1756] Alkylation takes place in the γ position, but the double bond migrates out of conjugation with the COOEt unit [$BrCH_2CH{=}CHCOOEt \rightarrow RCH{=}CHCH_2COOEt$]. In this case, however, double-bond

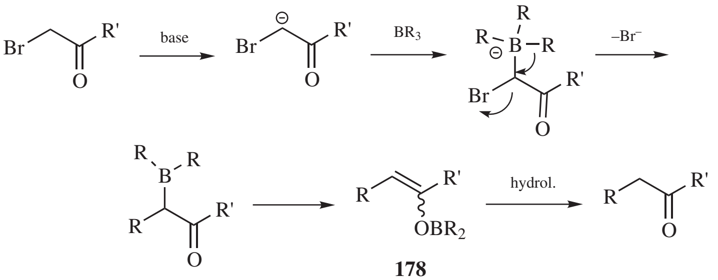
migration is an advantage, because nonconjugated β,γ-unsaturated esters are usually much more difficult to prepare than their α,β-unsaturated isomers.

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H.C. Brown[1757] (see also, **15-16**, **15-27**, **18-31-18-40**, and so on). These compounds are extremely versatile and can be used for the preparation of many types of compounds. In this reaction, for example, an alkene (through the BR_3 prepared from it) can be coupled to a ketone, a nitrile, a carboxylic ester, or a sulfonyl derivative. Note that this is still another indirect way to alkylate a ketone (see **10-68**) or a carboxylic acid (see **10-70**), and provides an additional alternative to the malonic ester and acetoacetic ester syntheses (**10-67**).

Although superficially this reaction resembles **10-57** it is likely that the mechanism is quite different, involving migration of an R group from boron to carbon (see also, **18-23–18-26**). The mechanism is not known with certainty,[1758] but it may be tentatively shown as (illustrated for an α-halo ketone):



178

The first step is removal of the acidic proton by the base to give an enolate anion that combines with the borane (Lewis acid–base reaction). An R group then migrates, displacing the halogen leaving group.[1759] Another migration follows, this time of BR_2 from carbon to oxygen to give the enol borinate **178**,[1760] which is hydrolyzed. Configuration at R is retained.[1761]

[1757]Brown, H.C. *Organic Syntheses via Boranes*, Wiley, NY, ***1975***; *Hydroboration*, W.A. Benjamin, NY, ***1962***; *Boranes in Organic Chemistry*, Cornell University Press, Ithaca, NY, ***1972***; Pelter, A.; Smith, K.; Brown, H.C. *Borane Reagents*, Academic Press, NY, ***1988***.

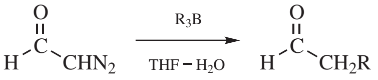
[1758]See Prager, R.H.; Reece, P.A. *Aust. J. Chem.* ***1975***, *28*, 1775.

[1759]It has been shown that this migration occurs stereospecifically with inversion in the absence of a solvent, but nonstereospecifically in the presence of a solvent, such as THF or dimethyl sulfide: Midland, M.M.; Zolopa, A.R.; Halterman, R.I. *J. Am. Chem. Soc.* ***1979***, *101*, 248. See also, Midland, M.M.; Preston, S.B. *J. Org. Chem.* ***1980***, *45*, 747.

[1760]Pasto, D.J.; Wojtkowski, P.W. *Tetrahedron Lett.* ***1970***, 215, Pasto, D.J.; Wojtkowski, P.W. *J. Org. Chem.* ***1971***, *36*, 1790.

[1761]Brown, H.C.; Rogić, M.M.; Rathke, M.W.; Kabalka, G.W. *J. Am. Chem. Soc.* ***1969***, *91*, 2150.

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes (**179**)[1762] react with trialkylboranes in a similar manner.



179

The mechanism is probably also similar. In this case a base is not needed, since the carbon already has an available pair of electrons. The reaction with diazo aldehydes[1763] is especially notable, since successful reactions cannot be obtained with α-halo aldehydes.[1764]

OS **VI**, 919; **IX**, 107.

10-74 Alkylation at an Alkynyl Carbon

Alkynyl-de-halogenation

$$\mathrm{RX} + \mathrm{R'C{\equiv}C^-} \longrightarrow \mathrm{RC{\equiv}CR'}$$

The reaction between alkyl halides and acetylide ions is useful but of limited scope.[1765] Only primary halides unbranched in the β-position give good yields, although allylic halides can be used if CuI is present.[1766] If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides[1767] are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base such as $NaNH_2$. Magnesium acetylides (ethynyl Grignard reagents; prepared as in **12-22**) are also frequently used, although they react only with active substrates, such as allylic, benzylic, and propargylic halides, and not with primary alkyl halides. Alternatively, the alkyl halide can be treated with a lithium acetylide–ethylenediamine complex.[1768] If 2 equivalents of a very

strong base are used, alkylation can be effected at a carbon α to a terminal triple bond: $RCH_2C{\equiv}CH + 2BuLi \rightarrow RCHC{\equiv}C^- + R'Br \rightarrow RR'CHC{\equiv}C^-$.[1769] For another method of alkylating at an alkynyl carbon, see **18-26**. An alternative method for generating an alkyne anion treated a trialkylsilyl alkyne with potassium carbonate in methanol, and then methyllithium/LiBr.[1770] In the presence of an alkyl iodide, alkylation at the alkynyl carbon occurred.

Alkynes couple with alkyl halides in the presence of SmI_2/Sm.[1771] Alkynes react with hypervalent iodine compounds[1772] and with reactive alkanes such as adamantane in the presence of AIBN.[1773] The reaction of benzylic amines with terminal alkynes, in the presence of copper triflate and *tert*-butylhydroperoxide leads to incorporation of the alkyne group α to the nitrogen.[1774] A similar reaction occurs at a methyl group of *N,N*-dimethylaniline.[1775] α-Methoxycarbamates (MeO—CHR—NR^1—CO_2R^2) react with terminal alkynes and CuBr to give the alkynylamine.[1776] In the presence of $GaCl_3$, $ClC{\equiv}CSiMe_3$ reacts with silyl enol ethers to give, after treatment with methanolic acid, an α-ethynyl ketone.[1777]

1-Haloalkynes (R—C≡C—X) react with $ArSnBu_3$ and CuI to give R—C≡C—Ar.[1778] Organozirconium compounds react in a similar manner.[1779] Acetylene reacts with 2 equivalents of iodobenzene, in the presence of a palladium catalyst and CuI, to give 1,2-diphenylethyne.[1780] 1-Trialkylsilyl alkynes react with 1-haloalkynes, in the presence of a CuCl catalyst, to give diynes[1781] and with aryl triflates to give 1-aryl alkynes.[1782]

In a related reaction, terminal alkynes react with silanes (R_3SiH) in the presence of an iridium catalyst to give the 1-trialkylsilyl alkyne.[1783] similar products are obtained when terminal alkynes react with *N*-trialkylsilylamines and $ZnCl_2$.[1784]

10-75 Preparation of Nitriles

Cyano-de-halogenation

$$RX + {}^{-}CN \longrightarrow RCN$$

The reaction between cyanide ion and alkyl halides is a convenient method for the preparation of nitriles.[1785] Primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. A number of solvents have been used, but the high yields and short reaction times observed with DMSO make it a very good solvent for this reaction.[1786] Other ways to obtain high yields under mild conditions are to use a phase-transfer catalyst,[1787] in alternative solvents, such as PEG 400 (a polyethylene glycol),[1788] or with ultrasound.[1789] This is an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (**16-4**).

The cyanide ion is an ambident nucleophile (it can react via N or via C) and isocyanides (also called isonitriles, R—N≡C) may be side products.[1790] If the preparation of isocyanides is desired, they can be made the main products by the use of reagents with more covalent metal–carbon bonds, such as silver or copper(I) cyanide[1791] (p. 515). However, the use on an excess of LiCN in acetone/THF gave the nitrile as the major product.[1792] Tosyl cyanide ($TolSO_2CN$) has been used in some cases.[1793]

Vinylic bromides can be converted to vinylic cyanides with CuCN,[1794] with KCN, a crown ether, and a Pd(0) complex,[1795] or with KCN and a Ni(0)

catalyst.[1796] Halides can be converted to the corresponding nitriles by treatment with trimethylsilyl cyanide in the presence of catalytic amounts of $SnCl_4$: $R_3CCl + Me_3\ SiCN \rightarrow R_3CCN$.[1797] Primary, secondary, and tertiary alcohols are converted to nitriles in good yields by treatment with NaCN, Me_3SiCl, and a catalytic amount of NaI in DMF—MeCN.[1798] Lewis acids have been used in conjunction with NaCN or KCN.[1799] α,β-Epxoy amides were opened to the β-cyano-α-hydroxyamide with Et_2AlCN.[1800] Cyanohydrins react with alkyl halides in some cases to give the nitrile.[1801]

Substrates that react with cyanide may contain leaving groups other than halides, such as esters of sulfuric and sulfonic acids (sulfates and sulfonates, respectively). Vinylic triflates give vinylic cyanides when treated with LiCN, a crown ether, and a palladium catalyst.[1802] Epoxides give β-hydroxy nitriles. The C-2-selectivity was observed when NaCN and $B(OMe)_3$ were reacted with a disubstituted epoxide.[1803] The use of trimethylsilyl cyanide (Me_3SiCN) and a Lewis acid generates the *O*-TMS β-hydroxy nitrile, and the use of $YbCl_3$ and a salen complex gave good enantioselectivity.[1804] One alkoxy group of acetals is replaced by CN [$R_2C(OR')_2 \rightarrow R_2C(OR')CN$] with Me_3SiCN and a catalyst[1805] or with *t*-BuNC and $TiCl_4$.[1806] Tetrabutylammonium cyanide converted a primary alcohol to the corresponding nitrile in the presence of PPh_3/DDQ.[1807]

Sodium cyanide in HMPA selectively cleaves methyl esters in the presence of ethyl esters:

$$RCOOMe + CN^- \longrightarrow MeCN + RCOO^-.$$ [1808]

10-76 Direct Conversion of Alkyl Halides to Aldehydes and Ketones

Formyl-de-halogenation

$$RX + Na_2Fe(CO)_4 \xrightarrow{PPh_3} \underset{\mathbf{180}}{RCOFe(CO)_3PPh_3^-} \xrightarrow{HOAc} RCHO$$

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished[1809] by treatment with sodium tetracarbonylferrate(-2)[1810] (*Collman's reagent*) in the presence of triphenylphosphine and subsequent quenching of **180** with acetic acid. The reagent $Na_2Fe(CO)_4$ can be prepared by treatment of iron pentacarbonyl $Fe(CO)_5$ with sodium amalgam in THF. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is generally not satisfactory for benzylic bromides, but a good yield of the ketone was obtained using benzyl chloride and aryl iodides.[1811] The initial species produced from RX and $Na_2Fe(CO)_4$ is the ion $RFe(CO)_4^-$ (which can be isolated[1812]); it then reacts with Ph_3P to give **180**.[1813]

The synthesis can be extended to the preparation of ketones in six distinct ways.[1814] These include quenching **180** with a second alkyl halide (R′X) rather than acetic acid; omitting PPh_3 with first RX and then adding the second, R′X; treatment with RX in the presence of CO,[1810] followed by treatment with R′X'; treatment with an acyl halide followed by treatment with an alkyl halide or an epoxide, gives an α,β-unsaturated ketone.[1815] The final variations involve reaction of alkyl halides or tosylates with $Na_2Fe(CO)_4$ in the presence of ethylene to give alkyl ethyl ketones;[1816] when 1,4-dihalides are used, five-membered cyclic ketones are prepared.[1817]

[1812]Siegl, W.O.; Collman, J.P. *J. Am. Chem. Soc.* ***1972***, *94*, 2516.

[1813]For the mechanism of the conversion $RFe(CO)_4^- \rightarrow$ **180**, see Collman, J.P.; Finke, R.G.; Cawse, J.N.; Brauman, J.I. *J. Am. Chem. Soc.* ***1977***, *99*, 2515; ***1978***, *100*, 4766.

[1814]For the first four of these methods, see Collman, J.P.; Winter, S.R.; Clark, D.R. *J. Am. Chem. Soc.* ***1972***, *94*, 1788; Collman, J.P.; Hoffman, N.W. *J. Am. Chem. Soc.* ***1973***, *95*, 2689.

[1815]Yamashita, M.; Yamamura, S.; Kurimoto, M.; Suemitsu, R. *Chem. Lett.* ***1979***, 1067.

[1816]Cooke, Jr., M.P.; Parlman, R.M. *J. Am. Chem. Soc.* ***1975***, *97*, 6863. The reaction was not successful for higher alkenes, except that where the double bond and the tosylate group are in the same molecule, five- and six-membered rings can be closed: see McMurry, J.E.; Andrus, A. *Tetrahedron Lett.* ***1980***, *21*, 4687, and references cited therein.

[1817]Yamashita, M.; Uchida, M.; Tashika, H.; Suemitsu, R. *Bull. Chem. Soc. Jpn.* ***1989***, *62*, 2728.

Yet another approach uses electrolysis conditions with the alkyl chloride, $Fe(CO)_5$ and a nickel catalyst and gives the ketone directly, in one step.[1818] In the first stage of methods 1, 2, and 3, primary bromides, iodides, and tosylates and secondary tosylates can be used. The second stage of the first four methods requires more active substrates, such as primary iodides or tosylates or benzylic halides. Method 5 has been applied to primary and secondary substrates.

Other acyl organometallic reagents are known. An acyl zirconium reagent, such as $RCOZr(Cl)Cp_2$, reacted with allylic bromide in the presence of CuI to give the corresponding ketone, but with allylic rearrangement.[1819]

Symmetrical ketones R_2CO can be prepared by treatment of a primary alkyl or benzylic halide with $Fe(CO)_5$ and a phase transfer catalyst,[1820] or from a halide RX (R = primary alkyl, aryl, allylic, or benzylic) and CO by an electrochemical method involving a nickel complex.[1821] Aryl, benzylic, vinylic, and allylic halides have been converted to aldehydes by treatment with CO and Bu_3SnH, with a Pd(0) catalyst.[1822] Various other groups do not interfere. Several procedures for the preparation of ketones are catalyzed by palladium complexes. Alkyl aryl ketones are formed in good yields by treatment of a mixture of an aryl iodide, an alkyl iodide, and a Zn—Cu couple with CO ($ArI + RI + CO \rightarrow RCOAr$).[1823] Vinylic halides react with vinylic tin reagents in the presence of CO to give unsymmetrical divinyl ketones.[1824] Aryl, vinylic, and benzylic halides can be converted to methyl ketones ($RX \rightarrow RCOMe$) by reaction with (α-ethoxyvinyl)tributyltin Bu_3Sn-$C(OEt){=}CH_2$.[1825] In addition, SmI_2 can be used to convert alkyl chloride to ketones, in the presence of 50 atm of CO.[1826] Carbonylation can also be done with Zn/CuI,[1827] Zn, and then $CoBr_2$,[1828] or with AIBN and $(Me_3Si)_3SiH$.[1829]

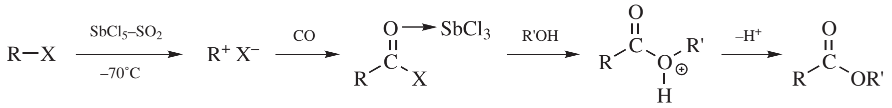
10-77 Carbonylation of Alkyl Halides, Alcohols, or Alkanes

Alkoxycarbonyl-de-halogenation

$$RX + CO + R'OH \xrightarrow[-70^\circ C]{SbCl_5-SO_2} RCOOR'$$

A direct method for preparing a carboxylic acid treats an alkyl halide with $NaNO_2$ in acetic acid and DMSO.[1830] Reaction of an alkyl halide with ClCO-CO_2Me and $(Bu_3Sn)_2$ under photochemical conditions leads to the corresponding methyl ester.[1831]

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain extended by one carbon.[1832] When an alkyl halide is treated with $SbCl_5$—SO_2 at −70°C, it dissociates into the corresponding carbocation (p. 236). If carbon monoxide and an alcohol are present, a carboxylic ester is formed by the following route:[1833]



This has also been accomplished with concentrated H_2SO_4 saturated with CO.[1834] Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen, using HF—SbF_5—CO.[1835]

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Alcohols with more than seven

carbons are cleaved into smaller fragments by this procedure.[1836] Similarly, tertiary alcohols[1837] react with H_2SO_4 and CO (which is often generated from HCOOH and the H_2SO_4 in the solution) to give trisubstituted acetic acids in a process called the *Koch–Haaf reaction* (see also, **15-35**).[1838] If a primary or secondary alcohol is the substrate, the carbocation initially formed rearranges to a tertiary ion before reacting with the CO. Better results are obtained if trifluoromethanesulfonic acid F_3CSO_2OH is used instead of H_2SO_4.[1839] Iodo alcohols were transformed into lactones under radical conditions (AIBN, allyl$SnBu_3$) and 45 atm of CO.[1840]

Another method[1841] for the conversion of alkyl halides to carboxylic esters is treatment of a halide with nickel carbonyl $Ni(CO)_4$ in the presence of an alcohol and its conjugate base.[1842] When R′ is primary, RX may only be a vinylic or an aryl halide; retention of configuration is observed at a vinylic R. Consequently, a carbocation intermediate is not involved here. When R′ is tertiary, R may be primary alkyl as well as vinylic or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

$$\mathrm{RX} + \mathrm{Ni(CO)_4} \xrightarrow[\mathrm{R'OH}]{\mathrm{R'O^-}} \mathrm{RCOOR'}$$

Still another method for the conversion of halides to acid derivatives makes use of $Na_2Fe(CO)_4$. As described in **10-76**, primary and secondary alkyl halides and tosylates react with this reagent to give the ion $RFe(CO)_4^-$ or, if CO is present, the ion $RCOFe(CO)_4^-$. Treatment of $RFe(CO)_4^-$ or $RCOFe(CO)_4^-$ with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.[1843] Alternatively, $RFe(CO)_4^-$ or $RCOFe(CO)_4^-$ reacts with a halogen (e.g., I_2) in the presence of an

alcohol to give a carboxylic ester,[1844] or in the presence of a secondary amine or water to give, respectively, the corresponding amide or free acid. The compound $RFe(CO)_4^-$ and $RCOFe(CO)_4^-$, what are prepared from primary R, give high yields. With secondary R, the best results are obtained in the solvent THF by the use of $RCOFe(CO)_4^-$ prepared from secondary tosylates. Ester and keto groups may be present in R without being affected. Carboxylic esters RCO_2R' have also been prepared by treating primary alkyl halides RX with alkoxides $R'O^-$ in the presence of $Fe(CO)_5$.[1845] $RCOFe(CO)_4^-$ is presumably an intermediate.

Palladium complexes also catalyze the carbonylation of halides.[1846] Aryl (see **13-15**),[1847] vinylic,[1848] benzylic, and allylic halides (especially iodides) can be converted to carboxylic esters with CO, an alcohol or alkoxide, and a palladium complex.[1849] Similar reactivity was reported with vinyl triflates.[1850] α-Halo ketones are converted to β-keto esters with CO, an alcohol, NBu_3 and a palladium catalyst at 110°C.[1851] Use of an amine instead of the alcohol or alkoxide leads to an amide.[1852]

Reaction with an amine, AIBN, CO and a tetraalkyltin catalyst also leads to an amide.[1853] Benzylic and allylic halides were converted to carboxylic acids electrocatalytically, with CO and a cobalt imine complex.[1854] Vinylic halides were similarly converted with CO and nickel cyanide, under phase-transfer conditions.[1855] Allylic *O*-phosphates were converted to allylic amides with CO and ClTi=NTMS, in the presence of a palladium catalyst.[1856] Terminal alkynes were converted to the alkynyl ester using CO, $PdBr_2$, $CuBr_2$ in methanol and sodium bicarbonate.[1857]

Other organometallic reagents can be used to convert alkyl halides to carboxylic acid derivatives. Benzylic halides were converted to carboxylic esters with CO in the presence of a rhodium complex.[1858] Variations introduce the R′ group via an ether R'_2O,[1859] a borate ester $B(OR')_3$,[1860] or an Al, Ti, or Zr alkoxide.[1861] The reaction of an alkene, a primary alcohol and CO, in the presence of a rhodium catalyst, led to carbonylation of the alkene and formation of the corresponding ester.[1862] Vinyl triflates were converted to the conjugated carboxylic acid with CO_2 and a nickel catalyst.[1863] Hydrogen peroxide with a catalytic amount of Na_2WO_4•2 H_2O converted benzylic chlorides to the corresponding benzoic acid.[1864] Reaction with an α,ω-diiodide, Bu_4NF and $Mo(CO)_6$ gave the corresponding lactone.[1865]

Reaction of an alkyl halide with $(MeS)_3C$—Li followed by aqueous HBF_4 leads to a thioester.[1866]

A number of double carbonylations have been reported. In these reactions, two molecules of CO are incorporated in the product, leading to α-keto acids or their derivatives.[1867] When the catalyst is a palladium complex, best results are obtained in the formation of α-keto amides.[1868] R is usually aryl or vinylic.[1869] The formation

CHAPTER 11

Aromatic Substitution, Electrophilic

Most substitutions at an aliphatic carbon are by nucleophiles. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring leads to its reactivity as a Lewis base or a Brønsted–Lowry base, depending on the positive species. In electrophilic substitutions, a positive ion or the positive end of a dipole or induced dipole is attacked by the aromatic ring. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitutions, the chief leaving groups are those best able to carry the unshared pair: Br^-, H_2O, OTs^-, and so on., that is, the weakest bases. In electrophilic substitutions the most important leaving groups are those that can best exist without the pair of electrons necessary to fill the outer shell, that is, the weakest Lewis acids.

MECHANISMS

Electrophilic aromatic substitutions are unlike nucleophilic substitutions in that the large majority proceed by just one mechanism with respect to the substrate.[1] In this mechanism, which we call the *arenium ion mechanism*, the electrophile (which can be viewed as a Lewis acid) is attacked by the π-electrons of the aromatic ring (behaving as a Lewis base in most cases) in the first step. This reaction leads to formation of a new C—X bond and a new sp^3 carbon in a positively charged intermediate called an arenium ion, where X is the electrophile. The positively charged intermediate (the arenium ion) is resonance stabilized, but not aromatic. Loss of a proton from the sp^3 carbon that is ‘‘adjacent’’ to the positive carbon in the arenium ion, in what is effectively an E1 process (see p. 1487), is driven by rearomatization of the ring from the arenium ion to give the aromatic substitution product. A proton

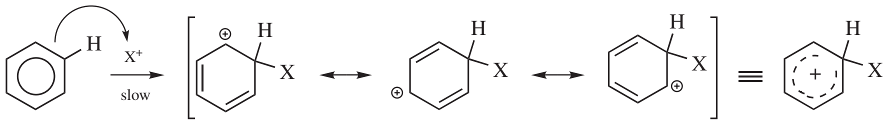
[1]For monographs, see Taylor, R. *Electrophilic Aromatic Substitution*, Wiley, NY, ***1990***; Katritzky, A.R.; Taylor, R. *Electrophilic Substitution of Heterocycles: Quantitative Aspects* (Vol. 47 of *Adv. Heterocycl. Chem.*), Academic Press, NY, ***1990***. For a review, see Taylor, R., in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 13, Elsevier, NY, ***1972***, pp. 1–406.

March's Advanced Organic Chemistry: Reactions, Mechanisms, and Structure, Sixth Edition, by Michael B. Smith and Jerry March
Copyright © 2007 John Wiley & Sons, Inc.

therefore becomes the leaving group in this overall transformation, where X replaces H. The IUPAC designation for this mechanism is $A_E + D_E$. Another mechanism, much less common, consists of the opposite behavior: a leaving group departs *before* the electrophile arrives. In this case, a substituent (*not* H) is attached to the aromatic ring, and the substituent is lost prior to incorporation of the electrophile. This mechanism, the S_E1 mechanism, corresponds to the S_N1 mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to S_N2) are not found at all. An addition–elimination mechanism has been postulated in one case (see **11-6**).

The Arenium Ion Mechanism[2]

In the arenium ion mechanism the electrophilic species may be produced in various ways, but when H is replaced by X conversion of the aromatic ring to an arenium ion is basically the same in all cases. For this reason, most attention in the study of this mechanism centers around the identity of the electrophilic entity and how it is produced.



1 **2**

The electrophile may be a positive ion or be a molecule that has a positive dipole. If it is a positive ion, it is attacked by the ring (a pair of electrons from the aromatic sextet is donated to the electrophile) to give a carbocation. This intermediate is a resonance hybrid as shown in **1**, but is often represented as in **2**. For convenience, the H atom to be replaced by X is shown in **1**. Ions of this type are called[3] *Wheland intermediates*, *σ complexes*, or *arenium ions*.[4] The inherent stability associated with aromaticity is no longer present in **1**, but the ion is stabilized by resonance. For this reason, the arenium ion is generally a highly reactive intermediate, although there are cases in which it has been isolated (see p. 661).

Carbocations can react in various ways (see p. 247), but for this type of ion the most likely pathway[5] is loss of either X^+ or H^+. In the second step of the

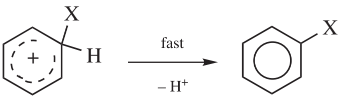
[2]This mechanism is sometimes called the S_E2 mechanism because it is bimolecular, but in this book we reserve that name for aliphatic substrates (see Chapter 12).

[3]General agreement on what to call these ions has not yet been reached. The term σ complex is a holdover from the time when much less was known about the structure of carbocations and it was thought they might be complexes of the type discussed in Chapter 3. Other names have also been used. We will call them arenium ions, following the suggestion of Olah, G.A. *J. Am. Chem. Soc.* ***1971***, *94*, 808.

[4]For reviews of arenium ions formed by addition of a proton to an aromatic ring, see Brouwer, D.M.; Mackor, E.L.; MacLean, C. in Olah, G.A.; Schleyer, P.V.R. *Carbonium Ions*, vol. 2, Wiley, NY, ***1970***, pp. 837–897; Perkampus, H. *Adv. Phys. Org. Chem.* ***1966***, *4*, 195.

[5]For a discussion of cases in which **1** stabilizes itself in other ways, see de la Mare, P.B.D. *Acc. Chem. Res.* ***1974***, *7*, 361.

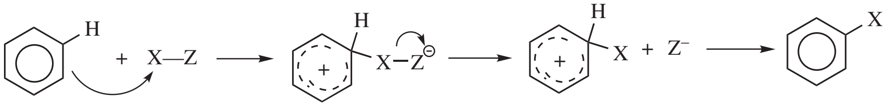
mechanism, the reaction proceeds with loss of the proton and the aromatic sextet is restored in the final product **3**.



3

The second step is nearly always faster than the first, making the first rate determining, and the reaction is second order. If formation of the attacking species is slower still, the aromatic compound does not take part in the rate expression at all. If X^+ is lost, there is no net reaction, but if H^+ is lost, an aromatic substitution has taken place and a base (generally the counterion of the electrophilic species although solvents can also serve this purpose) is necessary to help remove it.

If the attacking species is not an ion, but a dipole, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, as in the conversion of **4** to **5**. Note that when the aromatic ring attacks X, Z may be lost directly to give **5**.



4 **5**

The electrophilic entities and how they are formed are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

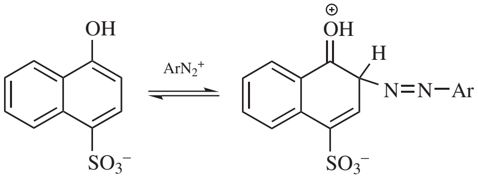
1. *Isotope Effects*. If the hydrogen ion departs before the arrival of the electrophile (S_E1 mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than non-deuterated compounds) because, in each case, the C—H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C—H bond is not broken in the rate-determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.[6] This result is incompatible with either the S_E1 or the simultaneous mechanism.

   However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the S_E1 or the simultaneous mechanisms (e.g., 1–3 for k_H/k_D instead of 6–7), we must look elsewhere for

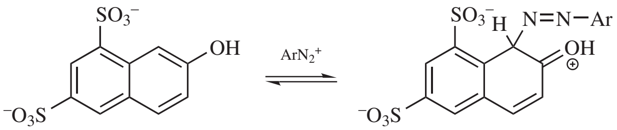
[6]The pioneering studies were by Melander, L. *Ark. Kemi* ***1950***, *2*, 213; Berglund-Larsson, U.; Melander, L. *Ark. Kemi* ***1953***, *6*, 219. See also, Zollinger, H. *Adv. Phys. Org. Chem.* ***1964***, *2*, 163.

the explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized:

Step 1 
Step 2 
The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect*.[7] The rate at which $ArHY^+$ reverts to ArH should be essentially the same as that at which $ArDY^+$ (or $ArTY^+$) reverts to ArD (or ArT), since the Ar—H bond is not cleaving. However, $ArHY^+$ should go to ArY faster than either $ArDY^+$ or $ArTY^+$, since the Ar—H bond is broken in this step. If $k_2 \gg k_{-1}$, this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step (k_1[ArH][Y^+]) and no isotope effect is predicted. However, if $k_2 \leq k_{-1}$, reversion to starting materials is important. If k_2 for $ArDY^+$ (or $ArTY^+$) is < k_2 for $ArHY^+$, but k_{-1} is the same, then a larger proportion of $ArDY^+$ reverts to starting compounds. That is, k_2/k_{-1} (the *partition factor)* for $ArDY^+$ is less than that for $ArHY^+$. Consequently, the reaction is slower for ArD than for ArH and an isotope effect is observed.



6 **7**



8 **9**

One circumstance that could affect the k_2/k_{-1} ratio is steric hindrance. Thus, diazonium coupling of **6** gave no isotope effect, while coupling of **8** gave a k_H/k_D ratio of 6.55.[8] For steric reasons, it is much more difficult for **9** to lose a proton (it is harder for a base to approach) than it is for **7**, so k_2 is greater for the latter. Since no base is necessary to remove ArN_2^+, k_{-1} does not depend on steric factors[9] and is about the same for each. Thus the partition factor k_2/k_{-1}

[7]For a discussion, see Hammett, L.P. *Physical Organic Chemistry*, 2nd ed., McGraw-Hill, NY, ***1970***, pp. 172–182.

[8]Zollinger, H. *Helv. Chim. Acta* ***1955***, *38*, 1597, 1617, 1623.

[9]Snyckers, F.; Zollinger, H. *Helv. Chim. Acta* ***1970***, *53*, 1294.

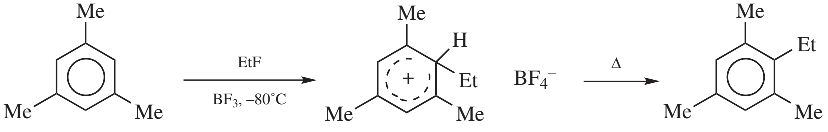
is sufficiently different for **7** and **9** that **8** exhibits a large isotope effect and **6** exhibits none.[10] Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

$$ArMR_3 + H_3O^+ \longrightarrow ArH + R_3MOH_2^+$$

where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions, the proton is the electrophile. If the arenium ion mechanism is operating, then the use of D_3O^+ should give rise to an isotope effect, since the D–O bond would be broken in the rate-determining step. Isotope effects of 1.55–3.05 were obtained,[11] in accord with the arenium ion mechanism.

2. *Isolation of Arenium Ion Intermediates*. Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.[12] For example, **7** was isolated as a solid with a



mesitylene **10** **11**

melting point of $-15°C$ from treatment of mesitylene with ethyl fluoride and the catalyst BF_3 at $-80°C$. When **10** was heated, the normal substitution product **11** was obtained.[13] Even the simplest such ion, the benzenonium ion (**12**), has been prepared in HF—SbF_5—SO_2ClF—SO_2F_2 at $-134°C$, where it could be studied

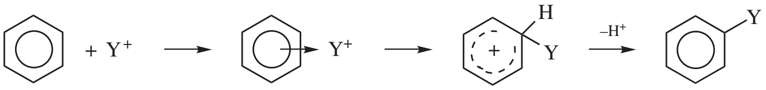
13

spectrally.[14] The ^{13}C NMR spectra of the benzenonium ion[15] and the pentamethylbenzenonium ion[16] give graphic evidence for the charge distribution shown in **1** (see the electron density map for the arenium ion, **13**). According to this, the 1, 3, and 5 carbons, each of which bears a positive charge of $+\frac{1}{3}$ [note that C-1,-3,-5 (numbering from **12**) are lighter,indicating less electron density in **13**, whereas C-2,-4 are darker for higher electron density], should have a greater chemical shift in the NMR than the 2 and 4 carbons, which are uncharged. The spectra bear this out. For example, ^{13}C NMR chemical shifts for **12** are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.[15]

In Chapter 3, it was mentioned that positive ions can form addition complexes with π systems. Since the initial step of electrophilic substitution involves attack of a positive ion by an aromatic ring, it has been suggested[17] that such a complex, called a π *complex* (represented as **14**), is formed first, and then is converted to the arenium ion **15**.[18] Stable solutions of arenium ions or π complexes (e.g., with Br_2, I_2,



14 **15**

picric acid, Ag^+, or HCl) can be formed.[19] For example, π complexes are formed when aromatic hydrocarbons are treated with HCl alone, but the use of HCl plus a

TABLE 11.1. Relative Stabilities of Arenium Ions and π Complexes and Relative Rates of Chlorination and Nitration[a]

Substituents	Relative Arenium Ion Stability[20]	Relative π-Complex Stability[20]	Rate of Chlorination[21]	Rate of Nitration[26]
None (benzene)	0.09	0.61	0.0005	0.51
Me	0.63	0.92	0.157	0.85
p-Me_2	1.00	1.00	1.00	1.00
o-Me_2	1.1	1.13	2.1	0.89
m-Me_2	26	1.26	200	0.84
1,2,4-Me_3	63	1.36	340	
1,2,3-Me_3	69	1.46	400	
1,2,3,4-Me_4	400	1.63	2,000	
1,2,3,5-Me_4	16,000	1.67	240,000	
Me_5	29,900		360,000	

[a]In each case, p-xylene = 1.00.

Lewis acid (e.g., $AlCl_3$) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity (showing positive and negative ions are present), while a π complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a π complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and $AlCl_3$ gives deuterium exchange. The relative stabilities of some methylated arenium ions and π complexes are shown in Table 11.1. The arenium ion stabilities listed were determined by the relative basicity of the substrate toward HF.[20] The π complex stabilities are relative equilibrium constants for the reaction[21] between the aromatic hydrocarbon and HCl. As shown in Table 11.1, the relative stabilities of the two types of species are very different: the π complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal. It is noted that stable arenium ions have been obtained from large methylene-bridged polycyclic aromatic hydrocarbons.[22]

How can we tell if **14** is present on the reaction path? If it is present, there are two possibilities: (*1*) The formation of **14** is rate determining (the conversion of **14** to **15** is much faster), or (*2*) the formation of **14** is rapid, and the conversion **14** to **15** is rate determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 11.1. We measure the relative rates of reaction of a given electrophile with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they

[20]Kilpatrick, M.; Luborsky, F.E. *J. Am. Chem. Soc.* ***1953***, *75*, 577.

[22]Laali, K.K.; Okazaki, T.; Harvey, R.G. *J. Org. Chem.* ***2001***, *66*, 3977.

resemble the stabilities of the π complexes, the latter are formed in the slow step.[23] When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not to the π complex stabilities. For example, Table 11.1 lists chlorination rates.[21] Similar results were obtained in room-temperature bromination with Br_2 in acetic acid[24] and in acetylation with CH_3CO^+ SbF_6^-.[25] It is clear that in these cases the π complex either does not form at all, or if it does, its formation is not rate determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO_2^+ (in the form of NO_2^+ BF_4^-), the relative rates resembled π complex stabilities much more than arenium ion stabilities (Table 11.1).[26] Similar results were obtained for bromination with Br_2 and $FeCl_3$ in nitromethane. These results were taken to mean[27] that in these cases π complex formation is rate determining. However, graphical analysis of the NO_2^+ data showed that a straight line could not be drawn when the nitration rate was plotted against π complex stability,[28] which casts doubt on the rate-determining formation of a π complex in this case.[29] There is other evidence, from positional selectivities (discussed on p. 682), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate determining with powerful electrophiles. Not much is known about this intermediate, which is given the nondescriptive name *encounter complex* and generally depicted as **16**. The arenium complex mechanism is therefore written as[30]

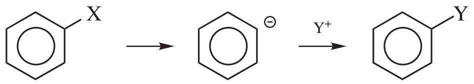
For the reason given above and for other reasons, it is unlikely that the encounter complex is a π complex, but just what kind of attraction exists between Y^+ and ArH is not known, other than the presumption that they are together within a solvent cage (see also p. 682). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that π complexes are present on the pathway from substrate to arenium ion in the gas-phase protonation of alkylbenzenes.[31]

The S_E1 Mechanism

The S_E1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see **11-33**, **11-35**) or when a very strong base is present (see **11-1**, **11-10**, and **11-39**).[32] It consists of two steps with an intermediate carbanion. The IUPAC designation is $D_E + A_E$.



Reactions **12-41**, **12-45**, and **12-46** also take place by this mechanism when applied to aryl substrates.

ORIENTATION AND REACTIVITY

Orientation and Reactivity in Monosubstituted Benzene Rings[33]

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the ortho, meta, or para position and the substitution may be slower or faster than with benzene itself. The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that increase the reaction rate are called *activating* and those that slow it *deactivating*. Some groups are predominantly meta directing; all of these are deactivating. Others are mostly ortho-para directing; some of these are deactivating too, but most are activating. Groups direct *predominantly*, but usually not *exclusively*. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the ortho, and 1% of the para isomer.

The orientation and reactivity effects are explained on the basis of resonance and field effects of each group on the stability of the intermediate arenium ion. To understand why we can use this approach, it is necessary to know that in these reactions

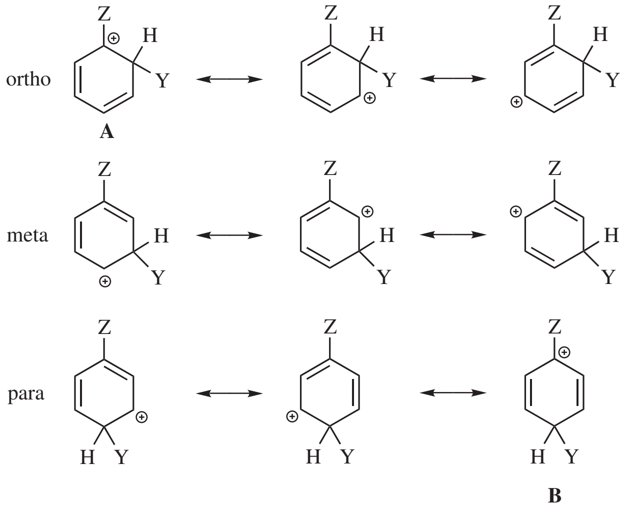
[31]Holman, R.W.; Gross, M.L. *J. Am. Chem. Soc.* ***1989***, *111*, 3560.

[32]It has also been found with a metal ($SnMe_3$) as electrofuge: Eaborn, C.; Hornfeld, H.L.; Walton, D.R.M. *J. Chem. Soc. B* ***1967***, 1036.

[33]For a review of orientation and reactivity in benzene and other aromatic rings, see Hoggett, J.G.; Moodie, R.B.; Penton, J.R.; Schofield, K. *Nitration and Aromatic Reactivity*, Cambridge University Press, Cambridge, ***1971***, pp. 122–145, 163–220.

the product is usually kinetically and not thermodynamically controlled (see p. 307). Some of the reactions are irreversible and the others are usually stopped well before equilibrium is reached. *Therefore, which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products, but on the activation energy necessary to form each of the three intermediates.* It is not easy to predict which of the three activation energies is lowest, but we make the assumption that the free-energy profile resembles either Fig. 6.2(*a* or *b*). In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the Hammond postulate (p. 308), we can then assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of the intermediate will also lower the activation energy necessary to attain it. Since the intermediate, once formed, is rapidly converted to products, we can use the relative stabilities of the three intermediates as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, we may get product ratios that are quite different. For example, the sulfonation of naphthalene at 80°C, where the reaction does not reach equilibrium, gives mostly α-naphthalenesulfonic acid,[34] while at 160°C, where equilibrium is attained, the β isomer predominates[35] (the α isomer is thermodynamically less stable because of steric interaction between the SO_3H group and the hydrogen at the 8 position).

The three possible ions from incorporation of Y at the ortho, meta, and para positions are shown, and each arenium in obviously has a positive charge in the ring.



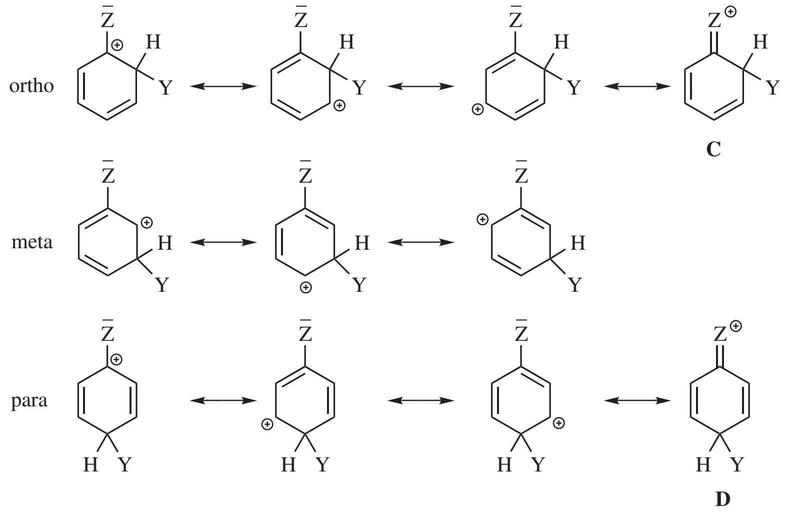
We can therefore predict that any group Z that has an electron-donating field effect (+*I*, Z will have a − charge or a δ− dipole in most cases) should stabilize all three

[34]Fierz, H.E.; Weissenbach, P. *Helv. Chim. Acta* ***1920***, *3*, 312.
[35]Witt, O.N. *Berchti* ***1915***, *48*, 743.

ions (relative to **1**), since electron donation to a positive center is stabilizing. On the other hand, electron-withdrawing groups (*−I*, Z will have a + charge or a δ+ dipole in most cases) will increase the positive charge on the ring (like charges repel), and destabilize the arenium ion. Formation of a stabilized ion should be faster than benzene (which generates **1**), or activating, but formation of a destabilized ion should be slower, or deactivating. Such field effects should taper off with distance and are thus strongest at the carbon connected to the group Z (known as the ipso carbon). Of the three arenium ions, only the ortho and para have any positive charge at this carbon. None of the canonical forms of the meta ion has a positive charge at the ipso carbon. Therefore, *+I* groups should stabilize all three ions but mostly the ortho and para, so they should be not only activating but ortho–para-directing as well. On the other hand, *−I* groups, by removing electron density, should destabilize all three ions but mostly the ortho and para, and should be not only deactivating but also meta-directing.

These conclusions are correct as far as they go, but they do not lead to the proper results in all cases. In many cases, there is *resonance interaction* between Z and the ring; this also affects the relative stability, in some cases in the same direction as the field effect, in others differently.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. The three arenium ions would then look like this:



For each ion the same three canonical forms can be drawn as before, but now we can draw an extra form for the ortho and para ions. The stability of these two ions is increased by the extra form not only because it is another canonical form, but because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except of course hydrogen) in these forms (**C** and **D**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the meta isomer. The inclusion of this form in

the hybrid lowers the energy not only because of rule 6 (p. 47), but also because it spreads the positive charge over a larger area—out onto the group Z. Groups with a pair of electrons (e.g., as the halogens) to contribute would be expected, then, in the absence of field effects, not only to direct ortho and para, but also to activate these positions for electrophilic attack.

On the basis of these discussions, we can distinguish three types of groups.

1. Groups that contain an unshared pair of electrons on the atom connected to the ring. In this category are O^-, NR_2, NHR, NH_2,[36] OH, OR, NHCOR, OCOR, SR, and the four halogens.[37] The halogens deactivate the aromatic ring to substitution (the rate of reaction is slower than that of benzene), and this effect may arise from the unique energy level of the halogen lone-pair orbital, which is higher than the adjacent π-molecular orbital of benzene (π_1).[38] The widely held explanation for this, however, is that the halogens have a $-I$ effect. The SH group would probably belong here too, except that in the case of thiophenols electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates. [39] The resonance explanation predicts that all these groups should be ortho–para directing, and they are, though all except O^- are electron withdrawing by the field effect (p. 20). Therefore, for these groups, resonance is more important than the field effect. This is especially true for NR_2, NHR, NH_2, and OH, which are *strongly* activating, as is O^-. The other groups are mildly activating, except for the halogens, which are deactivating. Fluorine is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally. In order to explain why chlorine, bromine, and iodine deactivate the ring, even though they direct ortho–para, we must assume that the canonical forms **C** and **D** make such great contributions to the respective hybrids that they make the ortho and para arenium ions more stable than the meta, even though the $-I$ effect of the halogen is withdrawing sufficient electron density from the ring to deactivate it. The three halogens make the ortho and para ions more stable than the meta, but less stable than the unsubstituted arenium ion (**1**). For the other groups that contain an unshared pair, the ortho and para ions are more stable than either the meta ion or the unsubstituted ion. For most of

[36]It must be remembered that in acid solution amines are converted to their conjugate acids, which for the most part are meta-directing (type 2). Therefore in acid (which is the most common medium for electrophilic substitutions) amino groups may direct meta. However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, ortho-para direction is often found even under acidic conditions.

[37]For a review of the directing and orienting effects of amino groups, see Chuchani, G., in Patai's. *The Chemistry of the Amino Group*, Wiley, NY, ***1968***, pp. 250–265; for ether groups see Kohnstam, G.; Williams, D.L.H., in Patai's. *The Chemistry of the Ether Linkage*, Wiley, NY, ***1967***, pp. 132–150.

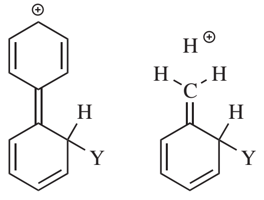
[38]Tomoda, S.; Takamatsu, K.; Iwaoka, M. *Chem. Lett.* ***1998***, 581.

[39]Tarbell, D.S.; Herz, A.H. *J. Am. Chem. Soc.* ***1953***, *75*, 4657. Ring substitution *is* possible if the SH group is protected. For a method of doing this, see Walker, D. *J. Org. Chem.* ***1966***, *31*, 835.

the groups in this category, the meta ion is more stable than **1**, so that groups, such as NH_2 and, OH, activate the meta positions too, but not as much as the ortho and para positions (see also the discussion on pp. 677–679).

2. Groups that lack an unshared pair on the atom connected to the ring and that are *−I*. In this category are, in approximate order of decreasing deactivating ability, NR_3^+, NO_2, CF_3,[40] CN, SO_3H, CHO, COR, COOH, COOR, $CONH_2$, CCl_3, and NH_3^+. Also in this category are all other groups with a positive charge on the atom directly connected to the ring[41] (SR_2^+, PR_3^+, etc.) and many groups with positive charges on atoms farther away, since often these are still powerful *−I* groups. The field-effect explanation predicts that these should all be meta directing and deactivating, and (except for NH_3^+) this is the case. The NH_3^+ group is an anomaly, since this group directs para about as much as or a little more than it directs meta.[42] The NH_2Me^+, $NHMe_2^+$, and NMe_3^+ groups all give more meta than para substitution, the percentage of para product decreasing with the increasing number of methyl groups.[43]

3. Groups that lack an unshared pair on the atom connected to the ring and that are ortho–para directing. In this category are alkyl groups, aryl groups, and the COO^- group,[44] all of which activate the ring. We will discuss them separately. Since aryl groups are *−I* groups, they might seem to belong to category 2. They are nevertheless ortho–para directing and activating. This can be explained in a similar manner as in category 1, with a pair of electrons from the aromatic sextet playing the part played by the unshared pair, so



E **F**

that we have forms like **E**. The effect of negatively charged groups like COO^- is easily explained by the field effect (negatively charged groups are of

[40]For the long-range electron-withdrawing effects of this group, see Castagnetti, E.; Schlosser, M. *Chem. Eur. J.* ***2002***, *8*, 799.

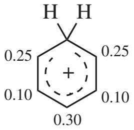
[44]Spryskov, A.A.; Golubkin, L.N. *J. Gen. Chem. USSR* ***1961***, *31*, 833. Since the COO^- group is present only in alkaline solution, where electrophilic substitution is not often done, it is seldom met with.

course electron donating), since there is no resonance interaction between the group and the ring. The effect of alkyl groups can be explained in the same way, but, in addition, we can also draw canonical forms, even though there is no unshared pair. These of course are hyperconjugation forms like **F** (see p. 669). This effect, like the field effect, predicts activation and ortho–para direction, so that it is not possible to say how much each effect contributes to the result. Another way of looking at the effect of alkyl groups (which sums up both field and hyperconjugation effects) is that (for Z = R) the ortho and para arenium ions are more stable because each contains a form (**A** and **B**) that is a tertiary carbocation, while all the canonical forms for the meta ion and for **1** are secondary carbocations. In activating ability, alkyl groups usually follow the Baker–Nathan order (p. 96), but not always.[45]

The Ortho/Para Ratio[46]

When an ortho–para-directing group is on a ring, it is usually difficult to predict how much of the product will be the ortho isomer and how much the para isomer. Indeed, these proportions can depend greatly on the reaction conditions. For example, chlorination of toluene gives an ortho/para ratio anywhere from 62:38 to 34:66.[47] Nevertheless, certain points can be made. On a purely statistical basis there would be 67% ortho and 33% para, since there are two ortho positions and only one para. However, the phenonium ion



12

12, which arises from protonation of benzene, has the approximate charge distribution shown[48] (see **13** as well). If we accept this as a model for the arenium ion in aromatic substitution, a para substituent would have a greater stabilizing effect on the adjacent carbon than an ortho substituent. If other effects are absent, this would mean that >33% para and <67% ortho substitution would be found. In hydrogen exchange (reaction **11-1**), where other effects are absent, it has been found for a number of substituents that the average ratio of the logarithms of the partial rate

[45]For examples of situations where the Baker–Nathan order is not followed, see Eaborn, C.; Taylor, R. *J. Chem. Soc.* ***1961***, 247; Utley, J.H.P.; Vaughan, T.A. *J. Chem. Soc. B* ***1968***, 196; Schubert, W.M.; Gurka, D.F. *J. Am. Chem. Soc.* ***1969***, *91*, 1443; Himoe, A.; Stock, L.M. *J. Am. Chem. Soc.* ***1969***, *91*, 1452.

[46]For a discussion, see Pearson, D.E.; Buehler, C.A. *Synthesis* ***1971***, 455 see pp 455–464. For a discussion of the influence of reaction conditions on the ortho/para ratio, see Effenberger, F.; Maier, A.J. *J. Am. Chem. Soc.* ***2001***, *123*, 3429.

factors for these positions (see p. 677 for a definition of partial rate factor) was close to 0.865,[49] which is not far from the value predicted from the ratio of charge densities in **12**. This picture is further supported by the fact that meta-directing groups, which destabilize a positive charge, give ortho/para ratios >67:33[50] (of course the total amount of ortho and para substitution with these groups is small, but the *ratios* are generally >67:33). Another important factor is the steric effect. If either the group on the attacking ring or the group on the electrophile is large, steric hindrance inhibits formation of the ortho product and increases the amount of the para isomer. An example may be seen in the nitration, under the same conditions, of toluene and *tert*-butylbenzene. The former gave 58% of the ortho compound and 37% of the para, while the more bulky *tert*-butyl group gave 16% of the ortho product and 73% of the para.[51] Some groups are so large that they direct almost entirely para.

When the ortho–para-directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of para product at the expense of the ortho. A comparison of the intermediates involved (p. 667) shows that **C** is a canonical form with an ortho-quinoid structure, while **D** has a para-quinoid structure. Since we know that para-quinones are more stable than the ortho isomers, it seems reasonable to assume that **D** is more stable than **C**, and therefore contributes more to the hybrid and increases its stability compared to the ortho intermediate.

It has been shown that it is possible to compel regiospecific para substitution by enclosing the substrate molecules in a cavity from which only the para position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Fig. 3.4). With a high enough concentration of cyclodextrin, it was possible to achieve a para/ortho ratio of 21.6[52] (in the absence of the cyclodextrin the ratio was only 1.48). This behavior is a model for the regioselectivity found in the action of enzymes.

Ipso Attack

We have discussed orientation in the case of monosubstituted benzenes entirely in terms of attachment at the ortho, meta, and para positions, but attachment at the

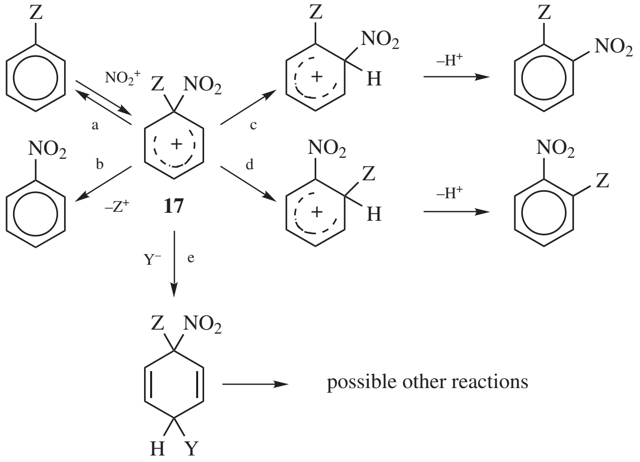
position bearing the substituent (called the *ipso position*[53]) can also be important. Ipso attack has mostly been studied for nitration.[54] When attack of NO_2^+ leads to incorporation at the ipso position there are at least five possible fates for the resulting arenium ion (**17**).



Path a. The arenium ion can lose NO_2^+ and revert to the starting compounds. This results in no net reaction and is often undetectable.

Path b. The arenium ion can lose Z^+, in which case this is simply aromatic substitution with a leaving group other than H (see **11-33–11-41**).

Path c. The electrophilic group (in this case NO_2^+) can undergo a 1,2-migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attachment of NO_2^+ at the ortho position of PhZ. It is not always easy to tell how much of the ortho product in any individual case arises from this pathway,[55] though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relat'ive reactivity of the ortho, meta, and para positions are cast into doubt, since some of the product may have arisen not from direct attachment at the ortho position, but from attachment at the ipso position followed by rearrangement.[56]

Path d. The ipso substituent (Z) can undergo 1,2-migration, which also produces the ortho product (though the rearrangement would become apparent if there

[56]This was first pointed out by Myhre, P.C. *J. Am. Chem. Soc.* ***1972***, *94*, 7921.

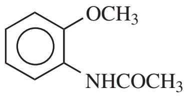
were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is NO_2^+.[57]

Path e. Attack of a nucleophile on **17**. In some cases, the products of such an attack (cyclohexadienes) have been isolated[58] (this is 1,4-addition to the aromatic ring), but further reactions are also possible.

Orientation in Benzene Rings With More Than One Substituent[59]

It is often possible in these cases to predict the correct isomer. In many cases, the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (ortho to one group and para to the other), but not at the 5 position (meta to both). Likewise, the incoming group in *p*-chlorobenzoic acid goes to the position ortho to the chloro and meta to the carboxyl group.

When the groups oppose each other, predictions may be more difficult. In a case such as where two



groups of about equal directing ability are in competing positions, all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution ortho to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly ortho and para to the *hydroxyl* group and not to the methyl. For this purpose we can arrange the groups in the following order: NH_2, OH, NR_2, O^- > OR, OCOR, NHCOR > R, Ar > halogen > meta-directing groups.
2. All other things being equal, a third group is least likely to enter between two groups in the meta relationship. This is the result of steric hindrance and increases in importance with the size of the groups on the ring and with the size of the attacking species.[60]

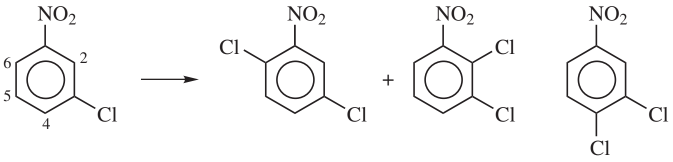
[57]For examples of such migration, where Z = Me, see Hartshorn, M.P.; Readman, J.M.; Robinson, W.T.; Sies, C.W.; Wright, G.J. *Aust. J. Chem.* ***1988***, *41*, 373.

[58]For examples, see Banwell, T.; Morse, C.S.; Myhre, P.C.; Vollmar, A. *J. Am. Chem. Soc.* ***1977***, *99*, 3042; Fischer, A.; Greig, C.C. *Can. J. Chem.* ***1978***, *56*, 1063.

[59]For a quantitative discussion, see pp. 677–678.

[60]In some cases, attack at an electrophile preferentially leads to attachment at the position between two groups in the meta relationship. For a list of some of these cases and a theory to explain them, see Kruse, L.I.; Cha, J.K. *J. Chem. Soc., Chem. Commun.* ***1982***, 1333.

3. When a meta-directing group is meta to an ortho–para-directing group, the incoming group primarily goes ortho to the meta-directing group rather than para. For example, chlorination of **18** gives mostly **19**.



18 **19** **20** **21**

The importance of this effect is underscored by the fact that **20**, which is in violation of the preceding rule, is formed in smaller amounts, but **21** is not formed at all. This is called the *ortho effect*,[61] and many such examples are known.[62] Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed ortho to it rather than para, even though this means that the group has to come in between two groups in the meta position. There is no good explanation yet for the ortho effect, though possibly there is intramolecular assistance from the meta-directing group.

It is interesting that chlorination of **18** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position rule 2, and the 4 position rule 3. The principal attachment is therefore at position 6.

Orientation in Other Ring Systems[63]

In fused ring systems, the positions are not equivalent and there is usually a preferred orientation, even in the unsubstituted hydrocarbon. The preferred positions may often be predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when attack by naphthalene leads to attachment of the electrophile at the α position than when attack by naphthalene leads to attachment of the electrophile at the β position. Therefore, the α position is the preferred site of attachment,[64] though, as previously mentioned (p. 666), the isomer formed by substitution at the β-position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly,

[61]This is not the same as the ortho effect mentioned on p. 412.

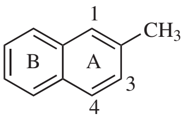
For a review of aromatic substitution on ferrocenes, see Bublitz, D.E.; Rinehart Jr., K.L. *Org. React.* ***1969***, *17*, 1.

[64]For a discussion on the preferred site of attachment for many ring systems, see de la Mare, P.B.D.; Ridd, J.H. *Aromatic Substitution Nitration and Halogenation*, Academic Press, NY, ***1959***, pp. 169–209.

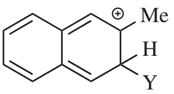
anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar,[65] in terms of mechanism, and rate data is available.[66] Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.[67] Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine,[68] it is not the free base that must attack the electrophile, but the conjugate acid (the pyridinium ion),[69] making the reactivity much less than that of benzene, being similar to that of nitrobenzene. The 3 position is most reactive in electrophilic substitution reactions of pyridine. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine *N*-oxide.[70] Note that calculations show that the 2-pyridyl and 2-pyrimidyl cations are best represented as *ortho*-hetarynium ions, being more stable than their positional, nonconjugated isomers by as much as 18–28 kcal mol^{-1} (75-11) kJ mol^{-1}.[71]

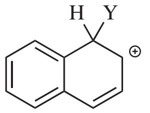
When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene (**22**) is activated by the methyl



22



23



24

group; ring B is not (though the presence of a substituent in a fused ring system affects all the rings,[72] the effect is generally greatest on the ring to which it is attached). We therefore expect substitution in ring A. The methyl group activates positions 1 and 3, which are ortho to itself, but not position 4, which is meta to it.

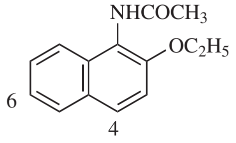
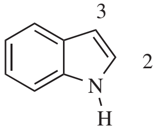
[72]See, for example, Ansell, H.V.; Sheppard, P.J.; Simpson, C.F.; Stroud, M.A.; Taylor, R. *J. Chem. Soc. Perkin Trans. 2* ***1979***, 381.

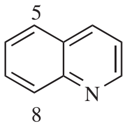
However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. All we can write are forms like **23**, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **24**) can be written in which ring B is benzenoid. We thus predict predominant substitution at C-1, and that is what is generally found.[73] However, in some cases predictions are much harder to make. For example, chlorination or nitration of **25** gives mainly the 4 derivative, but bromination yields chiefly the 6 compound.[74]



25

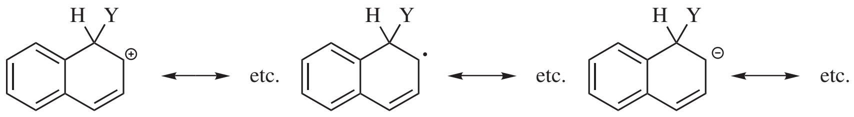


Indole



Quinoline

For fused heterocyclic systems too, we can often make predictions based on the above principles, though many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline generally reacts in the benzene ring, at the 5 and 8 positions, and slower than benzene, though faster than pyridine.



24 **26** **27**

In alternant hydrocarbons (p. 69), the reactivity at a given position is similar for electrophilic, nucleophilic, and free-radical substitution, because the same kind of resonance can be shown in all three types of intermediate (cf. **24**, **26**, and **27**). Attachment of the electrophile at the position that will best delocalize a positive charge will also best delocalize a negative charge or an unpaired electron. Most results are in accord with these predictions. For example, naphthalene is attacked primarily at the 1 position by NO_2^+, NH_2-, and Ph•, and always more readily than benzene.

[73]For example, see Alcorn, P.G.E.; Wells, P.R. *Aust. J. Chem.* ***1965***, *18*, 1377, 1391; Eaborn, C.; Golborn, P.; Spillett, R.E.; Taylor, R. *J. Chem. Soc. [74]Bell, F. *J. Chem. Soc.* ***1959***, 519.

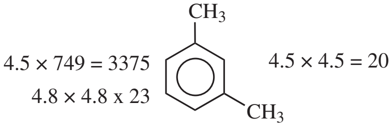
28

When strain due to a ring fused on an aromatic ring deforms that ring out of planarity, the molecule is more reactive to electrophilic aromatic substitution.[75] This has been explained by the presence of a shortened bond for the sp^2 hybridized carbon, increasing the strain at that position, and this is known as the *Mills–Nixon effect.*[76] There is EPR evidence (see p. 267) for 3,6-dimethyl-1,2,4,5-tetrahydrobenzo-bis (cyclobutene) (**28**) that supports the Mills–Nixon effect,[77] and a theoretical study supports this.[78] However, *ab initio* studies of triannelated benzene rings shows *no evidence* for the Mills–Nixon effect, and an new motif for bond-alternating benzenes was proposed.[79] Indeed, it is argued that the Mills–Nixon effect is not real.[80]

Quantitative Treatments of Reactivity in the Substrate

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogens that can leave, so that measurements of overall rate ratios do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position*. These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. We may thus define the *partial rate factor* for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation



of toluene the partial rate factors are: for the ortho position $o_f^{\mathrm{Me}} = 4.5$, for the meta $m_f^{\mathrm{Me}} = 4.8$, and for the para $p_f^{\mathrm{Me}} = 749$.[81] This means that toluene is acetylated at

[75]Taylor, R. *Electrophilic Aromatic Substitution*, Wiley, Chichester, ***1990***, pp. 53.

[79]Baldridge, K.K.; Siegel, J.J. *J. Am. Chem. Soc.* ***1992***, *114*, 9583.
[80]Siegel, J.S. *Angew. Chem. Int. Ed.* ***1994***, *33*, 1721.
[81]Brown, H.C.; Marino, G.; Stock, L.M. *J. Am. Chem. Soc.* ***1959***, *81*, 3310.

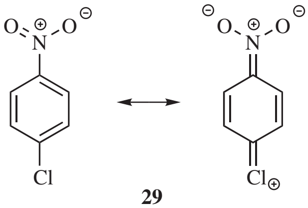
the ortho position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene. A partial rate factor >1 for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once we know the partial rate factors, we can predict the proportions of isomers to be obtained when two or more groups are present on a ring, *if we make the assumption that the effect of substituents is independent*. For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, we can calculate the theoretical partial rate factors at each position by multiplying those from toluene, so they should be as indicated:

TABLE 11.2. Calculated and Experimental Isomer Distributions in the Acetylation of *m*-Xylene[81]

	Isomer Distribution, %	
Position	Calculated	Observed
2	0.30	0
4	9.36	97.5
5	0.34	2.5

From this, it is possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors (in this case 1130), and the isomer distribution if the reaction is kinetically controlled. The overall rate ratio actually is 347[82] and the calculated and observed isomer distributions are listed in Table 11.2.[76] In this case, and in many others, agreement is fairly good, but many cases are known where the effects are not additive (as on p. 671).[83] For example, this treatment predicts that for 1,2,3-trimethylbenzene



29

[82]Marino, G.; Brown, H.C. *J. Am. Chem. Soc.* ***1959***, *81*, 5929.

[83]For some examples where additivity fails, see Fischer, A.; Vaughan, J.; Wright, G.J. *J. Chem. Soc. B* ***1967***, 368; Coombes, R.G.; Crout, D.H.G.; Hoggett, J.G.; Moodie, R.B.; Schofield, K. *J. Chem. Soc. B* ***1970***, 347; Richards, K.E.; Wilkinson, A.L.; Wright, G.J. *Aust. J. Chem.* ***1972***, *25*, 2369; Cook, R.S.; Phillips, R.; Ridd, J.H. *J. Chem. Soc. Perkin Trans. 2* ***1974***, 1166. For a theoretical treatment of why additivity fails, see Godfrey, M. *J. Chem. Soc. B* ***1971***, 1545.

there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects, such as those mentioned earlier (p. 673), by-products arising from ipso attack (p. 671) and by resonance interaction *between* groups (e.g., **29**), which must make the results deviate from simple additivity of the effects of the groups.

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other than hydrogen. By this means overall rate ratios can be measured for specific positions.[84] Results obtained in this way[85] give a reactivity order quite consistent with that for hydrogen as leaving group.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the hard–soft acid–base concept (p. 375).[86] From molecular-orbital theory, a quantity called *activation hardness* can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attachment at that position; hence the treatment predicts the most likely orientations for incoming groups.

A Quantitative Treatment of Reactivity of the Electrophile: The Selectivity Relationship

Not all electrophiles are equally powerful. The nitronium ion attacks not only benzene but also aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the power of the attacking group. The most obvious way to do this is with the Hammett equation (p. 392):

$$\log \frac{k}{k_0} = \rho\,\sigma$$

For aromatic substitution,[87] k_0 is divided by 6 and, for meta substitution, k is divided by 2, so that comparisons are made for only one position (consequently, k/k_0 for, say, the methyl group at a para position is identical to the partial rate factor p_f^{Me}). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron donating. However, if the equation is modified by the insertion of the Brown σ^+ values instead of the Hammett σ values (because a positive charge develops during the transition state), more satisfactory correlations can be made, even for electron-donating groups (see Table 9.4

TABLE 11.3. Relative Rates and Product Distributions in Some Electrophilic Substitutions on Toluene and Benzene[89]

Reaction	Relative Rate	Product Distribution, %	
	$k_{toluene}/k_{benzene}$	m	p
Bromination	605	0.3	66.8
Chlorination	350	0.5	39.7
Benzoylation	110	1.5	89.3
Nitration	23	2.8	33.9
Mercuration	7.9	9.5	69.5
Isopropylation	1.8	25.9	46.2

for a list of σ^+ values).[88] Groups with a negative value of σ_p^+ or σ_m^+ are activating for that position; groups with a positive value are deactivating. The ρ values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The ρ values vary not only with the electrophile, but also with conditions. A large negative value of ρ means an electrophile of relatively low reactivity. Of course, this approach is completely useless for ortho substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,[89] is based on the principle that reactivity of a species varies inversely with selectivity. Table 11.3 shows how electrophiles can be arranged in order of selectivity as measured by two indexes: (*1*) their selectivity in attacking toluene rather than benzene, and (*2*) their selectivity between the meta and para positions in toluene.[90] As the table shows, an electrophile more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *tert*-butyl cation is more stable and more selective than the isopropyl (p. 236), and Br_2 is more selective than Br^+. However, deviations from the relationship are known.[91] Selectivity depends not only on the nature of the electrophile but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the para and meta partial rate factors in toluene. He defined the selectivity S_f of a reaction as

$$S_f = \log \frac{p_f^{Me}}{m_f^{Me}}$$

[88]For a discussion of the limitations of the Hammett equation approach, see Koptyug, V.A.; Salakhutdinov, N.F.; Detsina, A.N. *J. Org. Chem. USSR* ***1984***, *20*, 1039.

[89]Stock, L.M.; Brown, H.C. *Adv. Phys. Org. Chem.* ***1963***, *1*, 35.

[90]Stock, L.M.; Brown, H.C. *Adv. Phys. Org. Chem.* ***1963***, *1*, 35, see p. 45.

[91]At least some of these may arise from migration of groups already on the ring; see Olah, G.A.; Olah, J.A.; Ohyama, T. *J. Am. Chem. Soc.* ***1984***, *106*, 5284.

That is, the more reactive an attacking species, the less preference it has for the para position compared to the meta. If we combine the Hammett–Brown $\sigma^+\rho$ relationship with the linearity between log S_f and log p_f^{Me} and between log S_f and log m_f^{Me}, it is possible to derive the following expressions:

$$\log p_f^{Me} = \frac{\sigma_p^+}{\sigma_p^+ - \sigma_m} S_f$$

$$\log m_f^{Me} = \frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} S_f$$

S_f is related to ρ by

$$S_f = \rho(\sigma_p^+ - \sigma_m^+)$$

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene. Examples of values for some reactions obtained from these equations are given in Table 11.4.[92] For other substituents, the treatment works well with groups that, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group.

Not only are there substrates for which the treatment is poor, but it also fails with very powerful electrophiles; this is why it is necessary to postulate the encounter complex mentioned on p. 664. For example, relative rates of nitration of *p*-xylene, 1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,[93] though the extra methyl groups should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every

TABLE 11.4. Values of m_f^{Me}, p_f^{Me}, S_f, and ρ for Three Reactions of Toluene[92]

Reaction	m_f^{Me}	p_f^{Me}	S_f	ρ
$PhMe + EtBr \xrightarrow[\text{benzene, 25°C}]{GaBr_3}$	1.56	6.02	0.587	−2.66
$PhMe + HNO_3 \xrightarrow[\text{45°C}]{\text{90\% HOAc}}$	2.5	58	1.366	−6.04
$PhMe + BR_2 \xrightarrow[\text{25°C}]{\text{85\% HOAc}}$	5.5	2420	2.644	−11.40

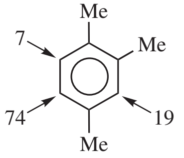
encounter[94] between an electrophile and substrate molecule)[95] that the presence of additional activating groups can no longer increase the rate.[96]

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.[97] Though



Relative rate ratios

steric effects are about the same at both positions, >10 times as much 5-nitro product was formed as 6-nitro product. It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (**12**, p. 664).[98] Since the position of attachment is not determined in the rate-determining step, the 5:6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier[99] and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a π complex, and we have seen (p. 664) that there is evidence against this.

One interesting proposal[100] is that the encounter pair is a radical pair $\overline{\mathrm{NO_2{\bullet}ArH{\bullet}^{+}}}$ formed by an electron transfer (SET), which would explain why the electrophile, once in the encounter complex, can acquire the selectivity that the free NO_2^+ lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical

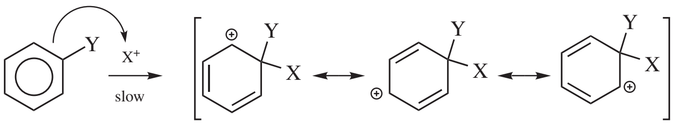
pair subsequently collapses to the arenium ion. There is evidence[101] both for and against this proposal.[102]

The Effect of the Leaving Group



30

In the vast majority of aromatic electrophilic substitutions, the leaving group is H^+ as indicated above, and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested:[103] (*1*) for leaving groups that depart without assistance (S_N1 process with respect to the leaving group), NO_2^+[104] $< i\text{Pr}^+ \sim SO_3 < t\text{-Bu}^+ \sim ArN_2^+ < ArCHOH^+ < NO^+ < CO_2$; (*2*) for leaving groups that depart with assistance from an outside nucleophile (S_N2 process), $Me^+ < Cl^+ < Br^+ < D^+ \sim RCO^+ < H^+ \sim I^+ < Me_3Si^+$. We can use this kind of list to help predict which group, X or Y, will cleave from an arenium ion **30** (see **1**, where Y = H) once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way: by influencing the rate at which attack of the original electrophile leads to attachment directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors (i_f^X).[53] Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo, *p*-bromo-, and *p*-chloroanisole, respectively.[105] This means, for example, that attack at the electrophile in this case leads to attachment at the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than attachment at the 4 position resulting from attack of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso

[101]For evidence in favor of the proposal, see Reents, Jr., W.D.; Freiser, B.S. *J. Am. Chem. Soc.* ***1980***, *102*, 271; Morkovnik, A.S.; Dobaeva, N.M.; Panov, V.B.; Okhlobystin, O.Yu. *Doklad. attack at the methyl position was 6.8 times slower than attack of phenol leading to attachment at the para position.[106] Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.[107]

REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

Hydrogen as the Leaving Group in Simple Substitution Reactions

A. Hydrogen as the Electrophile

11-1 Hydrogen Exchange

Deuterio-de-hydrogenation or Deuteriation

$$ArH + D^+ \rightleftharpoons ArD + H^+$$

Aromatic compounds can exchange hydrogens when treated with acids. The reaction is used chiefly to study mechanistic questions[108] (including substituent effects), but can also be useful to deuterate (add ^{2}H) or tritiate (add ^{3}H) aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D_2O gives slow exchange on heating, with only ortho and para hydrogens being exchanged.[109] Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is a great deal of evidence that exchange takes place by the ordinary arenium ion mechanism. Among the evidence are the orientation effects noted above and the finding that the reaction is general acid catalyzed, which means that a proton is transferred in the slow step[110] (p. 373). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.[4] Simple aromatic compounds can be extensively deuterated in a convenient fashion by

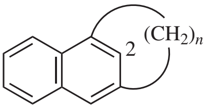
treatment with D_2O and BF_3.[111] It has been shown that tritium exchange takes place readily at the 2 position of **31**, despite the fact that this position is hindered by the bridge. The rates were not very different from the comparison compound 1,3-dimethylnaphthalene.[112]



n=7, 8, 10

31

Hydrogen exchange can also be effected with strong bases,[113] such as NH_2-. In these cases, the slow step is the proton transfer:

$$\text{ArH} + \text{B} \longrightarrow \text{Ar}^- + \text{BH}^+$$

so the S_E1 mechanism and not the usual arenium ion mechanism is operating.[114] Aromatic rings can also be deuterated by treatment with D_2O and a rhodium(III) chloride[115] or platinum[116] catalyst or with C_6D_6 and an alkylaluminum dichloride catalyst,[117] though rearrangements may take place during the latter procedure. Tritium (^3H, abbreviated T) can be introduced by treatment with T_2O and an alkylaluminum dichloride catalyst.[117] Tritiation at specific sites (e.g., >90% para in toluene) has been achieved with T_2 gas and a microporous aluminophosphate catalyst.[118]

Most aromatic compounds, whether of high or low reactivity, can be nitrated, because a wide variety of nitrating agents is available.[119] For benzene, the simple alkylbenzenes, and less reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids,[120] but for active substrates, the reaction can be carried out with nitric acid alone,[121] or in water, acetic acid, acetic anhydride, or chloroform.[122] Nitric acid in acetic anhydride/trifluoroacetic anhydride on zeolite H-β was used to convert toluene to 2,4-dinitrotoluene,[123] and $AcONO_2$ on clay converted ethylbenzene to ortho–para nitro ethylbenzene.[124] In fact, these milder conditions are necessary for active compounds, such as amines, phenols, and pyrroles, since reaction with mixed nitric and sulfuric acids would oxidize these substrates. With active substrates, such as amines and phenols, nitration can be accomplished by nitrosation under oxidizing conditions with a mixture of dilute nitrous and nitric acids.[125] A mixture of $NO_2/O_2/Fe(acac)_3$ can be used for active compounds,[126] as can $NaNO_2$ with trichloroisocyanuric acid on wet silica gel,[127] or N_2O_4 and silica acetate.[128] Trimethoxybenzenes were nitrated easily with ceric ammonium nitrate on silica gel,[129] and mesitylene was nitrated in an

ionic liquid using nitric acid–acetic anhydride.[130] Phenol can be nitrated in an ionic liquid.[131]

If anhydrous conditions are required, nitration can be effected with N_2O_5[132] in CCl_4 in the presence of P_2O_5, which removes the water formed in the reaction.[133] These reagents can also be used with proton or Lewis acid catalysts. Representative nitrating agents are $NaNO_2$ and trifluoroacetic acid,[134] N_2O_4 (which gives good yields with polycyclic hydrocarbons[135]), N_2O_4/O_2 and a catalytic amount of zeolite Hβ,[136] $Yb(OTf)_3$,[137] and nitronium salts,[138] such as $NO_2^+BF_4^-$, $NO_2^+PF_6^-$, and $NO_2^+CF_3SO_3^-$.[139] A mixture of NO_2 and ozone has also been used.[140] Clays, such as clay-supported cupric nitrate (Claycop),[141,142] or Montmorillonite KSF—$Bi(NO_3)$[143] can be used to nitrate aromatic rings. Nitration of styrene poses a problem since addition occurs to the C=C unit to give a 1-nitroethyl aryl.[144] Heterocycles, such as pyridine, are nitrated with N_2O_5 and SO_2.[145] Deactivated aromatic rings, as in acetophenone, were nitrated with N_2O_5 and $Fe(acac)_2$.[146]

An alternative route for the nitration of activated aromatic compounds, such as anisole, used a nitrate ester ($RONO_2$) with triflic acid in an ionic liquid for ortho-selective nitration.[147] Nitration in alkaline media can be accomplished with esters of nitric acid, such as ethyl nitrate ($EtONO_2$).

When anilines are nitrated under strong acid conditions, meta orientation is generally observed, because the species undergoing nitration is actually the conjugate acid of the amine. If the conditions are less acidic, the free amine is nitrated and the orientation is ortho–para. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also p. 668). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (**16-72**) or acetic anhydride (**16-73**). Nitration of the resulting acetanilide derivative avoids all these problems. There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an *N*-nitro compound $Ar{-}NH{-}NO_2$ which rapidly undergoes rearrangement (see **11-28**) to give the product.[148]

Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has entered the ring, but a second and a third group can be introduced if desired, especially when an activating group is also present. Even *m*-dinitrobenzene can be nitrated if vigorous conditions are applied. This has been accomplished with $NO_2^+BF_4^-$ in FSO_3H at 150°C.[149]

With most of the reagents mentioned, the attacking species is the nitronium ion NO_2^+. Among the ways in which this ion is formed are

1. In concentrated sulfuric acid, by an acid–base reaction in which nitric acid is the base:

$$HNO_3 + 2\,H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2\,HSO_4^-$$

This ionization is essentially complete.

2. In concentrated nitric acid alone,[150] by a similar acid–base reaction in which one molecule of nitric acid is the acid and another the base:

$$2\,HNO_3 \rightleftharpoons NO_2^+ + NO_3^- + H_2O$$

This equilibrium lies to the left (~4% ionization), but enough NO_2^+ is formed for nitration to occur.

[147]In emim OTf, 1-ethyl-3-methylimidazolium triflate: Laali, K.K.; Gettwert, V.J. *J. Org. Chem.* ***2001***, *66*, 35.

[149]Olah, G.A.; Lin, H.C. *Synthesis* ***1974***, 444.

[150]See Belson, D.J.; Strachan, A.N. *J. Chem. Soc. Perkin Trans. 2* ***1989***, 15.

3. The equilibrium just mentioned occurs to a small extent even in organic solvents.
4. With N_2O_5 in CCl_4, there is spontaneous dissociation:

$$N_2O_5 \rightleftharpoons NO_2^+ + NO_3^-$$

but in this case there is evidence that some nitration also takes place with undissociated N_2O_5 as the electrophile.
5. When nitronium salts are used, NO_2^+ is of course present to begin with. Esters and acyl halides of nitric acid ionize to form NO_2^+. Nitrocyclohexadienones are converted to NO_2^+ and the corresponding phenol.[132]

There is a great deal of evidence that NO_2^+ is present in most nitration reactions and that it is the attacking entity,[151] for example,

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at 1400 cm^{-1} attributable to NO_2^+ and one at 1050 cm^{-1} due to HSO_4-.[152]
2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.[153] This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.
3. The fact that nitronium salts in which nitronium ion is known to be present (by X-ray studies) nitrate aromatic compounds shows that this ion does attack the ring.
4. The rate of the reaction with most reagents is proportional to the concentration of NO_2^+, not to that of other species.[154] When the reagent produces this ion in small amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids, the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents such as nitromethane, acetic acid, and CCl_4, the kinetics are first order in nitric acid alone and zero order in aromatic substrate, because the rate-determining step is formation of NO_2^+ and the substrate does not take part in this.

[151]For an exhaustive study of this reaction, see Hughes, E.D.; Ingold, C.K.in a series of several papers with several different co-workers, see *J. Chem. Soc.* ***1950***, 2400.

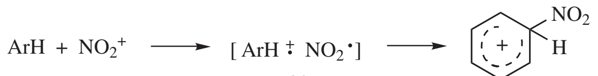
An interesting route to nitrobenzene begins with bromobenzene. Reaction with butyllithium gives phenyllithium, which reacts with an excess of N_2O_4 to give nitrobenzene.[155]

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (see p. 682) such as **32**.[156]



32

Arylboronic acids have been shown to react with ammonium nitrate and trifluoroacetic acid to give the corresponding nitrobenzene.[157]

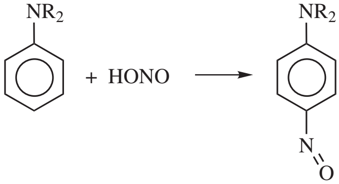
11-3 Nitrosation or Nitroso-de-hydrogenation



Ring nitrosation[158] with nitrous acid is normally carried out only with active substrates, such as amines and phenols. However, primary aromatic amines give diazonium ions (**13-19**) when treated with nitrous acid,[159] and secondary amines tend to give *N*-nitroso rather than *C*-nitroso compounds (**12-50**); hence this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless, secondary aromatic amines can be *C*-nitrosated in two ways. The *N*-nitroso compound first obtained can be isomerized to a *C*-nitroso compound (**11-29**), or it can be treated with another equivalent of nitrous acid to give an *N,C*-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was $CF_3COOH–CH_2Cl_2$.[160]

Much less work has been done on the mechanism of this reaction than on **11-2**.[161] In some cases, the attacking entity is NO^+, but in others it is apparently NOCl, NOBr, N_2O_3, and so on, in each of which there is a carrier of NO^+. Both NOCl and NOBr are formed during the normal process of making nitrous acid (the treatment of sodium nitrite with HCl or HBr). Nitrosation requires active substrates because NO^+ is much less reactive than NO_2^+. Kinetic studies have shown that NO^+ is at least 10^{14} times less reactive than NO_2^+.[162] A consequence of the relatively high stability of NO^+ is that this species is easily cleaved from the arenium ion, so that k_{-1} competes with k_2 (p. 660) and isotope effects are found.[163] With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed rearranges to the C-nitroso product.[164] Tertiary aromatic amines substituted in the ortho position generally do not react with HONO, probably because the ortho substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (p. 48).

11-4 Diazonium Coupling

Arylazo-de-hydrogenation

$$ArH + Ar'N_2^+ \longrightarrow Ar{-}N{=}N{-}Ar'$$

Aromatic diazonium ions normally couple only with active substrates, such as amines and phenols.[165] Many of the products of this reaction are used as dyes (*azo dyes*).[166] Presumably because of the size of the attacking species, substitution is mostly para to the activating group, unless that position is already occupied, in which case ortho substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give ortho and para products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the

[166]For reviews of azo dyes, see Zollinger, H. *Color Chemistry*, VCH, NY, ***1987***, pp. 85–148; Gordon, P.F.; Gregory, P. *Organic Chemistry in Colour*, Springer, NY, ***1983***, pp. 95–162.

reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide Ar—N=N—OH. Primary and secondary amines face competition from attack at the nitrogen.[167] However, the resulting *N*-azo compounds (aryl triazenes) can be isomerized to *C*-azo compounds (**11-30**). In at least some cases, even when the *C*-azo compound is isolated, it is the result of initial *N*-azo compound formation followed by isomerization. It is therefore possible to synthesize the *C*-azo compound directly in one laboratory step.[168] Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the para position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the ArN_2^+. Some coupling reactions which are otherwise very slow (in cases where the coupling site is crowded) are catalyzed by pyridine for reasons discussed on p. 661. Phase transfer catalysis has also been used.[169]

Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported. All the examples reported so far involve cyclopropanediazonium ions and bridgehead diazonium ions, in which loss of N_2 would lead to very unstable carbocations.[170] Azobenzenes have been prepared by Pd-catalyzed coupling of aryl hydrazides with aryl halides, followed by direct oxidation.[171]

The mechanism of Z/E isomerization in Ar-N=NAr systems has been studied.[172]

OS **I**, 49, 374; **II**, 35, 39, 145.

11-5 Direct Introduction of the Diazonium Group

Diazoniation or Diazonio-de-hydrogenation

$$\mathrm{ArH} \xrightarrow[\mathrm{HX}]{2\,\mathrm{HONO}} \mathrm{ArN_2^+X^-}$$

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.[173] The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in reaction **11-3**, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.[174] The reagent

(azidochloromethylene)dimethylammonium chloride [$Me_2N{=}C(Cl)N_3\ Cl^-$] can also introduce the diazonium group directly into a phenol.[175] A synthesis of solid aryldiazonium chlorides is now available.[176]

11-6 Amination or Amino-de-hydrogenation[177]

$$ArH + HN_3 \xrightarrow{AlCl_3} ArNH_2$$

Aromatic compounds can be converted to primary aromatic amines, in 10–65% yields, by treatment with hydrazoic acid HN_3 in the presence of $AlCl_3$ or H_2SO_4.[178] Higher yields (>90%) have been reported with trimethylsilyl azide (Me_3SiN_3) and triflic acid F_3CSO_2OH.[179] Treatment of an aromatic compound with tetramethylhydrazonium iodide and then ammonium also give the aryl amine.[180] Tertiary amines have been prepared in ~50–90% yields by treatment of aromatic hydrocarbons with *N*-chlorodialkylamines; by heating in 96% sulfuric acid; or with $AlCl_3$ or $FeCl_3$ in nitroalkane solvents; or by irradiation.[181] Treatment of an aryl halide with an amine and a palladium catalyst leads to the aniline derivative.[182]

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate to high yields by amination with an *N*-chlorodialkylamine (or an *N*-chloroalkylamine) and a metallic-ion catalyst (e.g., Fe^{2+}, Ti^{3+}, Cu^+, Cr^{2+}) in the presence of sulfuric acid.[183] The attacking species in this case is the aminium radical ion $R_2NH\bullet$ formed by[184]

$$R_2\overset{\oplus}{N}HCl \quad + \quad M^+ \longrightarrow R_2\overset{\oplus}{N}H\bullet \quad + \quad M^{2+} \quad + \quad Cl^-$$

Because attack is by a positive species (even though it is a free radical), orientation is similar to that in other electrophilic substitutions (e.g., phenol and acetanilide give ortho and para substitution, mostly para). When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only meta-directing groups do not give the reaction at all. Fused ring systems react well.[185]

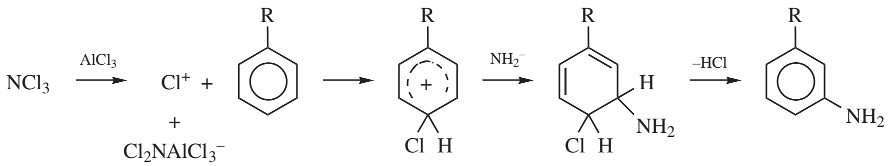
[184]For a review of aminium radical ions, see Chow, Y.L. *React. Intermed. (Plenum)* ***1980***, *1*, 151.

[185]The reaction has been extended to the formation of primary aromatic amines, but the scope is narrow: Citterio, A.; Gentile, A.; Minisci, F.; Navarrini, V.; Serravalle, M.; Ventura, S. *J. Org. Chem.* ***1984***, *49*, 4479.

Unusual orientation has been reported for amination with haloamines and with NCl_3 in the presence of $AlCl_3$. For example, toluene gave predominately meta amination.[186] It has been suggested that initial attack in this case is by Cl^+ and that a nitrogen nucleophile (whose structure is not known, but is represented here as NH_2^- for simplicity) adds to the resulting arenium ion, so that the initial reaction is addition to a carbon–carbon double bond followed by elimination of HCl from **33**.[187]



33

According to this suggestion, the electrophilic attack is at the para position (or the ortho, which leads to the same product) and the meta orientation of the amino group arises indirectly. This mechanism is called the *σ-substitution mechanism.*

Diphenylliodonium salts react with amines in the presence of a copper catalyst. Diphenyliodonium tetrafluoroborate, $Ph_2I^+BF_4^-$, reacts with indole in DMF at 150°C with a $Cu(OAc)_2$ catalyst, for example, to give *N*-phenylindole.[188]

Aromatic compounds that do not contain meta-directing groups can be converted to diarylamines by treatment with aryl azides in the presence of phenol at −60°C: $ArH + Ar'N_3 \rightarrow ArNHAr'$.[189] Diarylamines are also obtained by the reaction of *N*-arylhydroxylamines with aromatic compounds (benzene, toluene, anisole) in the presence of F_3CCOOH: $ArH + Ar'NHOH \rightarrow ArNHAr'$.[190]

Direct *amidation* can be carried out if an aromatic compound is heated with a hydroxamic acid (**34**) in polyphosphoric acid, but the scope is essentially limited to phenolic ethers.[191] The reaction of an aromatic compound with aniline, Bu_4NF and $KMnO_4$ led to the diarylamine.[192] The formation of hydroindole derivatives was accomplished by reaction of a *N*-carbamoyl phenylethylamine derivative with phenyliodine (III) diacetate, followed by Bu_4NF.[193] Direct amidation via ipso substitution by nitrogen was accomplished when a *N*-methoxy arylethylamide (**35**) was

C. Sulfur Electrophiles

11-7 Sulfonation or Sulfo-de-hydrogenation

$$ArH + H_2SO_4 \longrightarrow ArSO_2OH$$

The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused ring systems), aryl halides, ethers, carboxylic acids, amines,[197] acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.[198] Phenols can also be successfully sulfonated, but attack at oxygen may compete.[199] Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming sulfuric acid, SO_3, $ClSO_2OH$, $ClSO_2NMe_2$/In(OTf)$_3$,[200] or other reagents.[201] As with nitration (**11-2**), reagents of a wide variety of activity are available to suit both highly active and highly inactive substrates. Since this is a reversible reaction (see **11-38**), it may be necessary to drive the reaction to completion.

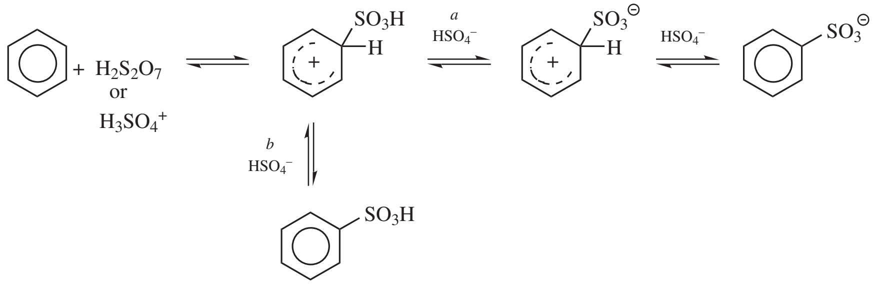
[201]For a reaction using silica sulfuric acid, see Hajipour, A.R.; Mirjalili, B.B.F.; Zarei, A.; Khazdooz, L.; Ruoho, A.E. *Tetrahedron Lett.* ***2004***, *45*, 6607.

However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.[202] Sulfur trioxide reacts much more rapidly than sulfuric acid with benzene it is nearly instantaneous. Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see **11-36**).

A great deal of work has been done on the mechanism,[203] chiefly by Cerfontain and co-workers. Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though SO_3 is involved in all cases, either free or combined with a carrier. In aqueous H_2SO_4 solutions, the electrophile is thought to be $H_3SO_4^+$ (or a combination of H_2SO_4 and H_3O^+) at concentrations below ~ 80–85% H_2SO_4, and $H_2S_2O_7$ (or a combination of H_2SO_4 and SO_3) at concentrations higher than this[204] (the change-over point varies with the substrate[205]). Evidence for a change in electrophile is that in the dilute and in the concentrated solutions the rate of the reaction was proportional to the activity of $H_3SO_4^+$ and $H_2S_2O_7$, respectively. Further evidence is that with toluene as substrate the two types of solution gave very different ortho/para ratios. The mechanism is essentially the same for both electrophiles and may be shown as:[204]



The other product of the first step is HSO_4^- or H_2O from $H_2S_2O_7$ or $H_3SO_4^+$, respectively. Path *a* is the principal route, except at very high H_2SO_4 concentrations, when path *b* becomes important. With $H_3SO_4^+$ the first step is rate determining under all conditions, but with $H_2S_2O_7$ the first step is the slow step only up to ~ 96% H_2SO_4, when a subsequent proton transfer becomes partially rate determining.[206] The $H_2S_2O_7$ is more reactive than $H_3SO_4^+$. In fuming sulfuric acid (H_2SO_4 containing excess SO_3), the electrophile is thought to be $H_3S_2O_7^+$ (protonated $H_2S_2O_7$) up to

~104% H_2SO_4 and $H_2S_4O_13$ ($H_2SO_4 + 3SO_3$) beyond this concentration.[207] Finally, when pure SO_3 is the reagent in aprotic solvents, SO_3 itself is the actual electrophile.[208] Free SO_3 is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate determining, at least in some solvents.

11-8 Halosulfonation or Halosulfo-de-hydrogenation

$$ArH + ClSO_2OH \longrightarrow ArSO_2Cl$$

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.[209] Since sulfonic acids can also be prepared by the same reagent (**11-7**), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.[210] The reaction has also been effected with bromo- and fluorosulfuric acids. Sulfinyl chlorides (ArSOCl) have been prepared by the reaction of thionyl chloride and an aromatic compound on Montmorillonite K10 clay.[211]

OS **I**, 8, 85.

11-9 Sulfonylation

Alkylsulfonylation or **Alkylsulfo-de-hydrogenation**

$$ArH + SOCl_2 \xrightarrow{TfOH} ArSOAr$$

$$ArH + Ar'SO_2Cl \xrightarrow{AlCl_3} ArSO_2Ar'$$

Diaryl sulfoxides can be prepared by the reaction of aromatic compounds with thionyl chloride and triflic acid.[212] Diaryl sulfones have also been prepared using thionyl chloride with the ionic liquid [bmim]Cl•$AlCl_3$.[213] Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a Friedel–Crafts catalyst[214] This reaction is analogous to Friedel–Crafts acylation with carboxylic acid halides (**11-17**). In a better procedure, the aromatic compound

is treated with an aryl sulfonic acid and P_2O_5 in polyphosphoric acid.[215] Still another method uses an arylsulfonic trifluoromethanesulfonic anhydride $ArSO_2OSO_2CF_3$ (generated *in situ* from $ArSO_2Br$ and CF_3SO_3Ag) without a catalyst.[216] Indium *tris*(triflate)[217] and indium trichloride[218] give sulfonation with sulfonyl chlorides, and indium bromide was used in indoles.[219] A ferric chloride catalyzed reaction with microwave irradiation has also been reported,[220] as has the use of zinc metal with microwave irradiation.[221]

The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.[222]

Direct formation of diaryl sulfones from benzenesulfonic acid and benzene was accomplished using Nafion-H.[223]

likely to be protonated by the liberated HX.[226] For this reason, primary amines are often converted to the corresponding anilides if monosubstitution is desired. With phenols it is possible to stop after one group has entered.[227] The rapid room-temperature reaction with amines and phenols is often used as a test for these compounds.

For less activated aromatic rings, iron was commonly used at one time for halogenation, but the real catalyst was shown not to be the iron itself, but rather the ferric bromide or ferric chloride formed in small amounts from the reaction between iron and the reagent. Indeed, ferric chloride and other Lewis acids are typically directly used as catalysts, as is iodine. For active substrates, including amines, phenols, naphthalene, and polyalkylbenzenes,[228] such as mesitylene and isodurene, no catalyst is needed. Many Lewis acids can be used, including thallium(III) acetate, which promotes bromination with high regioselectivity para to an ortho–para-directing group.[229] A mixture of $Mn(OAc)_3$ and acetyl chloride, with ultrasound, chlorinates anisole with high selectivity.[230] Bromination on NaY zeolite occurs with high para selectivity.[231]

Other acids can be used to promote chlorination or bromination. *N*-Bromosuccinimide and HBF_4 can be used to brominate phenols with high *para*-selectivity,[232] as can pyridinium bromide perbromide,[233] and NBS in acetic acid with ultrasound is effective.[234] The use of NBS with a catalytic amount of HCl has also been reported.[235] Both NCS and NBS with aqueous BF_3 gave the respective chloride or bromide.[236] Note that NBS in an ionic liquid[237] gave the brominated aromatic. Bromine on silica gel gave good yields of the brominated aromatic compound.[238] HBr with hydrogen peroxide

converted aniline to 2,4,6-tribromoaniline.[239] Majetich and co-workers reported the use of HBr/DMSO for the remarkably selective bromination of aniline.[240] *para*-Bromination of aniline was reported by mixing aniline with the ionic liquid, bmim Br_3.[241] Similarly, hmim Br_3[242] without another reagent is a brominating agent.

Other reagents have been used for chlorination and bromination, among them HOCl,[243] HOBr, and *N*-chloro and *N*-bromo amides (especially NBS and tetraalkylammonium polyhalides[244]). In all but the last of these cases, the reaction is catalyzed by the addition of acids. Sulfuryl chloride (SO_2Cl_2) in acetic acid effective chlorinates anisole derivatives,[245] and LiBr with ceric ammonium nitrate in acetonitrile brominates.[246] Acetyl chloride with a catalytic amount of ceric ammonium nitrate also converted aromatic compounds to the corresponding chlorinated derivative.[247] A mixture of KCl and Oxone® as chlorinated activated aromatic compounds.[248] Oxone® and KBr gave good para bromination of anisole.[249] Dibromoisocyanuric acid in H_2SO_4 is a very good brominating agent[250] for substrates with strongly deactivating substituents.[251] If the substrate contains alkyl groups, side-chain halogenation (**14-1**) is possible with most of the reagents mentioned, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible. Both NCS in isopropanol[252] and *tert*-butyl hypochlorite[253] chlorinate aniline derivatives, and $KBr/NaBO_3{\bullet}4\ H_2O$ has been used for the bromination of aniline derivatives.[254] Anisole was brominated with para selectivity using HBr, in the presence of *tert*-butyl hydroperoxide and hydrogen peroxide.[255] Potassium bromide (KBr) with a zeolite (HZSM-5), acetic acid and 30% hydrogen peroxide was used to brominate both anisole and aniline derivatives.[256] Conversion of aniline to the *N*-$SnMe_3$ derivative allowed

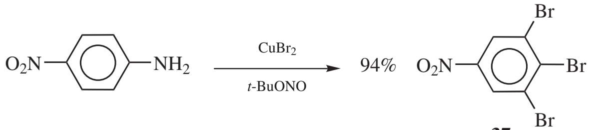
in situ bromination with bromine, with high para selectivity after conversion to the free amine with aqueous KF.[257] Pyridinium bromochromate converted phenolic derivatives to brominated phenols.[258]

Chlorine is a more active reagent than bromine. Phenols can be brominated exclusively in the ortho position (disubstitution of phenol gives 2,6-dibromophenol) by treatment with Br_2 at about $-70°C$, in the presence of *tert*-butylamine or triethylenediamine to precipitate out the liberated HBr.[259] Predominant ortho chlorination[260] of phenols has been achieved with chlorinated cyclohexadienes,[261] while para chlorination of phenols, phenolic ethers, and amines can be accomplished with *N*-chloroamines[262] and with *N*-chlorodimethylsulfonium chloride ($Me_2S^+Cl\,Cl^-$).[263] The last method is also successful for bromination when *N*-bromodimethylsufonium bromide is used. On the other hand, certain alkylated phenols can be brominated in the meta positions with Br_2 in the superacid solution SbF_5—HF.[264] It is likely that the meta orientation is the result of conversion by the super acid of the OH group to the OH_2^+ group, which should be meta directing because of its positive charge. Bromination and the Sandmeyer reaction (**14-20**) can be carried out in one laboratory step to give **37** by treatment of an aromatic primary amine with $CuBr_2$ and *tert*-butyl nitrite, for example[265]



37

With deactivated aromatic derivatives, such as nitrobenzene, BrF_3 and Br_2 is an effective reagent, gives the *meta*-brominated product.[266] Tetrabutylammonium bromide and P_2O_5 at 100°C has been used to convert 2-hydroxypyridine derivatives to the corresponding 2-bromopyridine.[267] Bromination at C-6 of 2-aminopyridine was accomplished with NBS.[268] An alternative route

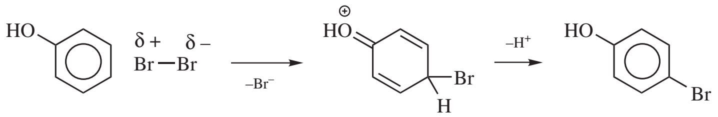
reacted pyridine *N*-oxide was $POCl_3$ and triethylamine to give 2-chloropyridine.[269] Pyridinium dichlorobromate with $FeCl_3$ brominates benzene.[270]

For reactions in the absence of a catalyst, the attacking entity is simply Br_2 or Cl_2 that has been polarized by the ring.[271]



38

Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into Cl^+ and Cl^-, the addition of chloride should decrease the rate and the addition of acids should increase it. Intermediate **38** has been detected spectrally in the aqueous bromination of phenol.[272]

When a Lewis acid catalyst is used with chlorine or bromine, the attacking entity may be Cl^+ or Br^+, formed by $FeCl_3 + Br_2 \rightarrow FeCl_3Br^- + Br^+$, or it may be Cl_2 or Br_2, polarized by the catalyst. With other reagents, the attacking entity in brominations may be Br^+ or a species, such as H_2OBr^+ (the conjugate acid of HOBr), in which H_2O is a carrier of Br^+.[273] With HOCl in water the electrophile may be Cl_2O, Cl_2, or H_2OCl^+; in acetic acid it is generally AcOCl. All these species are more reactive than HOCl itself.[274] It is extremely doubtful that Cl^+ is a significant electrophile in chlorinations by HOCl.[274] It has been demonstrated in the reaction between *N*-methylaniline and calcium hypochlorite that the chlorine attacking entity attacks the *nitrogen* to give *N*-chloro-*N*-methylaniline, which rearranges (as in **11-31**) to give a mixture of ring-chlorinated *N*-methylanilines in which the ortho isomer predominates.[275] In addition to hypohalous acids and metal hypohalites, organic hypohalites are reactive. An example is *tert*-butylhypobromite (*t*-BuOBr), which brominated toluene in the presence of zeolite HNaX.[276]

When chlorination or bromination is carried out at high temperatures (e.g., 300–400°C), ortho–para-directing groups direct meta and vice versa.[277] A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the S_E1 mechanism, for example, in the *t*-BuOK-catalyzed bromination of 1,3,5-tribromobenzene.[278]

Furan and thiophene are known to polymerize in the presence of strong acid, both Brønsted–Lowry and Lewis. For such highly reactive heteroaromatic systems, alternative halogenating reagents are commonly used. Furan was converted to 2-bromofuran with a bromine•dioxane complex, for example, at <0°C.[279] 3-Butylthiophene reacted with NBS/acetic acid to give 2-bromo-3-butylthiophene.[280] *N*-Methylpyrrole reacted with NBS and a catalytic amount of PBr_3, at $-78°C \rightarrow -10°C$, to give *N*-methyl-3-bromopyrrole.[281]

2. *Iodine*. Iodine is the least reactive of the halogens in aromatic substitution.[282] Except for active substrates, an oxidizing agent must normally be present to oxidize I_2 to a better electrophile.[283] Examples of such oxidizing agents are HNO_3, HIO_3, SO_3, MnO_2,[284] hypervalent iodine compounds, such as $PhI(OTf)_2$,[285] $NaIO_4$,[286] peroxyacetic acid, H_2O_2[287] peroxydisulfates,[288] and ammonium iodide with Oxone®.[289] The ICl is a better iodinating agent than iodine itself.[290] Among other reagents used have been IF (prepared directly from the elements),[291] and benzyltrialkylammonium dichloroiodate (which iodinates phenols, aromatic amines, and *N*-acylated aromatic amines,[292] as well

as unprotected aniline derivatives[293]). Iodination can also be accomplished by treatment of the substrate with NCI and sulfuric acid,[294] NIS and trifluoroacetic acid,[295] KI/KIO_3 in aqueous methanol,[296] I_2 in the presence of copper salts,[297] Al_2O_3,[298] and NaI with an iron catalyst.[299] Sodium periodate and iodine was used to iodinate β-carbolines.[300] Sodium iodide in liquid NO_2 can be used to iodinate aniline derivatives.[301] A solvent-free iodination was accomplished using $NaICl_2$ and an *N*-bromoammonium salt.[302] Another solvent-free iodination used I_2 with $Bi(NO_3)_3$ on silica gel.[303] Iodine with Selectfluor also leads to iodination of aromatic compounds.[304]

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive, except for active species, such as phenols, where there is good evidence that I_2 is the attacking entity.[305] There is evidence that AcOI may be the attacking entity when peroxyacetic acid is the oxidizing agent,[306] and I_3^+ when SO_3 or HIO_3 is the oxidizing agent.[307] The I^+ ion has been implicated in several procedures.[308] For an indirect method for accomplishing aromatic iodination, see **12-31**.

Note that conversion of aniline derivatives to the corresponding para aryllithium, followed by reaction with $B(OMe)_3$ and then bromine at −78°C gave *p*-bromoaniline.[309]

3. *Fluorine*. Direct fluorination of aromatic rings with F_2 is not feasible at room temperature, because of the extreme reactivity of F_2.[310] It has been accomplished at low temperatures (e.g., −70 to −20°C, depending on the

substrate),[311] but the reaction is not yet of preparative significance. Fluorination has also been reported with acetyl hypofluorite CH_3COOF (generated from F_2 and sodium acetate),[312] with XeF_2,[313] and with an *N*-fluoroperfluoroalkyl sulfonamide, for example $(CF_3SO_2)_2NF$.[314] Pyridine has been converted to 2-fluoropyridine with $F_2/I_2/NEt_3$ in 1,1,2-trichloro-1,2,2-trifluoroethane.[315] However, none of these methods seems likely to displace the Schiemann reaction (**13-23**; heating diazonium tetrafluoroborates) as the most common method for introducing fluorine into aromatic rings.

The overall effectiveness of reagents in aromatic substitution is $Cl_2 > BrCl > Br_2 > ICl > I_2$.

E. Carbon Electrophiles

In the reactions in this section, a new carbon–carbon bond is formed. With respect to the aromatic ring, they are electrophilic substitutions, because a positive species attacks the ring. We treat them in this manner because it is customary. However, with respect to the electrophile, most of these reactions are nucleophilic substitutions, and what was said in Chapter 10 is pertinent to them.

11-11 Friedel–Crafts Alkylation

Alkylation or **Alkyl-de-hydrogenation**

$$ArH + RCl \xrightarrow{AlCl_3} ArCl$$

The alkylation of aromatic rings, called *Friedel–Crafts alkylation*, is a reaction of very broad scope.[316] The most important reagents are alkyl halides, alkenes, and

[316]For a monograph, see Roberts, R.M.; Khalaf, A.A. *Friedel–Crafts Alkylation Chemistry*, Marcel Dekker, NY, ***1984***. For a treatise on Friedel–Crafts reactions in general, see Olah, G.A. *Friedel–Crafts and Related Reactions*, Wiley, NY, ***1963–1965***. Volume 1 covers general aspects, such as catalyst activity, intermediate complexes, and so on. Volume 2 covers alkylation and related reactions. In this volume, the various reagents are treated by the indicated authors as follows: alkenes and alkanes, Patinkin, S.H.; Friedman, B.S. pp. 1–288; dienes and substituted alkenes, Koncos, R.; Friedman, B.S. pp. 289–412; alkynes, Franzen, V. pp. 413–416; alkyl halides, Drahowzal, F.A. pp. 417–475; alcohols and ethers, Schriesheim, A. pp. 477–595; sulfonates and inorganic esters, Drahowzal, F.A. pp. 641–658. For a monograph in which five chapters of the above treatise are reprinted and more recent material added, see Olah, G.A. *Friedel–Crafts Chemistry*, Wiley, NY, ***1973***.

alcohols, but other types of reagent have also been employed.[316] Tertiary halides are particularly good substrates since they form relatively stable tertiary carbocations. *tert*-Butyl chloride reacts with phenetole in the presence of a $ReBr(CO)_5$ catalyst, for example, to give the 4-*tert*-butyl isomer as the major product.[317] When alkyl halides are used, the reactivity order is F > Cl > Br > I.[318] This trend can be seen in reactions of dihalo compounds, such as $FCH_2CH_2CH_2Cl$, which react with benzene to give $PhCH_2CH_2CH_2Cl$[319] when the catalyst is BCl_3. By the use of this catalyst, it is therefore possible to place a haloalkyl group on a ring (see also, **11-14**).[320] Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of an aromatic compound; it is usually not possible to stop the reaction earlier.[321] Thus, benzene with CH_2Cl_2 gives not $PhCH_2Cl$, but Ph_2CH_2; benzene with $CHCl_3$ gives Ph_3CH. With CCl_4, however, the reaction stops when only three rings have been substituted to give Ph_3CCl. Functionalized alkyl halides, such as $ClCH(SEt)CO_2Et$, undergo Friedel–Crafts alkylation.[322] Interestingly, benzyl chloride was converted to diphenylmethane in benzene at 130°C with 10 atm of CO,[323] and also with a $LiB(C_6F_5)_4$ catalyst.[324]

Alkenes are especially good alkylating agents, generally proceeding by formation of an intermediate carbocation that reacts with the electron rich aromatic ring, and the final product (**39**) incorporates a H and Ar from ArH to a C=C double bond. Many variations are possible. This reaction has been accomplished in an ionic liquid, using $Sc(OTf)_3$ as the catalyst.[325] Intramolecular versions lead to polycyclic aromatic compounds.[326] Benzene reacted with 1,2,3,6-tetrahydropyridine in the presence of trifluoromethanesulfonic acid to give 4-phenylpiperidine.[327]

When 4-methoxyphenol reacted with isobutylene (electrolysis with 3 *M* $LiClO_4$ in nitromethane and acetic acid, initial reaction with the phenolic oxygen generated an ether moiety and the resulting carbocation was attacked by the aromatic ring to form a benzofuran.[328] Acetylene reacts with 2 mol of aromatic compound to give 1,1-diarylethanes, and phenylacetylene reacted to give 1,1-diarylethenes with a $Sc(OTf)_3$ catalyst.[329] Variations are possible here as well. Phenol reacted with trimethylsilylethyne, in the presence of $SnCl_4$ and 50% BuLi, at 105°C, to give the 2-vinyl phenolic derivative.[330] A palladium-catalyzed reaction of ethyl propiolate and *p*-xylene, with trifluoroacetic acid, gave the 3-arylalkenyl ester.[331] A ruthenium catalyzed intramolecular reaction with a pendant alkyne unit led to a dihydronapthalene derivative.[332]

Alcohols are more active than alkyl halides, but if a Lewis acid catalyst is used more catalyst is required, since the catalyst complexes with the OH group. However, proton acids, such as H_2SO_4, are often used to catalyze alkylation with alcohols. An intramolecular cyclization was reported from an allylic alcohol, using P_2O_5, to give indene derivatives.[333] When carboxylic esters are the reagents, there is competition between alkylation and acylation (**11-17**). This competition can often be controlled by choice of catalyst, and alkylation is usually favored, but carboxylic esters are not often employed in Friedel–Crafts reactions. Other alkylating agents are ethers, thiols, sulfates, sulfonates, alkyl nitro compounds,[334] and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable here are ethylene oxide, which puts the CH_2CH_2OH group onto the ring,[335] and cyclopropyl[336] units. For all types of reagent the reactivity order is allylic $\sim$ benzylic $>$ tertiary $>$ secondary $>$ primary.

Regardless of which reagent is used, a catalyst is nearly always required.[337] Aluminum chloride and boron trifluoride are the most common, but many other Lewis acids have been used, and also proton acids, such as HF and H_2SO_4.[338] For active halides a trace of a less active catalyst, such as $ZnCl_2$, may be enough. For an unreactive halide, such as chloromethane, a more powerful catalyst, such as $AlCl_3$, is needed, and in larger amounts. In some cases, especially with alkenes, a Lewis acid catalyst causes reaction only if a small amount of proton-donating cocatalyst is present. Catalysts have been arranged in the following order of overall reactivity: $AlBr_3 > AlCl_3 > GaCl_3 > FeCl_3 > SbCl_5$[339]$> ZrCl_4, SnCl_4 > BCl_3, BF_3, SbCl_3$;[340] but the reactivity order in each case depends on the substrate, reagent, and conditions.

Alkyl mesylates undergo alkylation reaction with benzene rings in the presence of $Sc(OTf)_3$.[341] Allylic acetates undergo alkylation with $Mo(CO)_6$[342] and allylic chlorides react in the presence of $ZnCl_2/SiO_2$.[343] Montmorillonite clay (K10) is an effective medium for alkylation reactions.[344] Nafion-H, a super acidic perfluorinated resin sulfonic acid, is a very good catalyst for gas phase alkylations with alkyl halides, alcohols,[345] or alkenes.[346]

Friedel–Crafts alkylation is unusual among the principal aromatic substitutions in that the entering group is activating (the product is more reactive than the starting aromatic substrate), and di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl, isopropyl) is only ~1.5–3 times as fast as benzene for Friedel–Crafts alkylations,[347] so it is often possible to obtain high yields of monoalkyl product.[348] Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity, but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.[349] This factor can be removed by the use of a suitable solvent, by high temperatures, or by high–speed stirring.

[337]There are a few exceptions. Certain alkyl and vinylic triflates alkylate aromatic rings without a catalyst, see Gramstad, T.; Haszeldine, R.N. *J. Chem. Soc.* ***1957***, 4069; Olah, G.A.; Nishimura, J. *J. Am. Chem. Soc.* ***1974***, *96*, 2214; Stang, P.J.; Anderson, A.G. *J. Am. Chem. Soc.* ***1978***, *100*, 1520.

It is important to note that the OH, OR, NH_2, and so on groups do not facilitate the reaction, since most Lewis acid catalysts coordinate with these basic groups. Although phenols give the usual Friedel–Crafts reactions, orienting ortho and para, the reaction is very poor for aniline derivatives. However, amines can undergo the reaction if alkenes are used as reagents and aluminum anilides as catalysts.[350] In this method, the catalyst is prepared by treating the amine to be alkylated with $\frac{1}{3}$ equivalent of $AlCl_3$. A similar reaction can be performed with phenols, though here the catalyst is $Al(OAr)_3$.[351] Primary aromatic amines (and phenols) can be methylated regioselectively in the ortho position by an indirect method (see **11-23**). For an indirect method for regioselective ortho methylation of phenols (see p. 1247).

Naphthalene and other fused ring compounds are so reactive that they react with the catalyst, and therefore tend to give poor yields in Friedel–Crafts alkylation. Heterocyclic rings are also tend to be poor substrates for the reaction. Although some furans and thiophenes have been alkylated, polymerization is quite common, and a true alkylation of a pyridine or a quinoline has never been described.[352] *N*-Methylpyrrole reacted with the C=C unit of methacrolein in the presence of a chiral catalyst (a chiral Friedel–Crafts catalyst) to give the 2-alkylated pyrrole, with good enantioselectivity.[353] Alkylation at C-5 of 2-trimethylsilylfuran was accomplished using the carbocation $[(p\text{-MeOC}_6H_4)_2CH^+ \text{ OTf}]$ and Proton Sponge (see p. 386).[354] Although mechanistically different, an intramolecular cyclization of an *N*-allylic pyrrole was accomplished using a rhodium catalyst with 100 atm of CO/H_2.[355] Note that alkylation of pyridine and other nitrogen heterocycles can be accomplished by a free radical[356] (**14-19**) and by a nucleophilic method (**13-17**). A variation generates an electrophilic species on the aromatic substrate. The reaction of isoquinoline with $ClCO_2Ph$ and AgOTf, followed by reaction with an allylic silane, led to a 2-allylic dihydroisoquinoline.[357]

In most cases, meta-directing groups make the ring too inactive for alkylation. Nitrobenzene cannot be alkylated, and there are only a few reports of successful Friedel–Crafts alkylations when electron-withdrawing groups are present.[358] This is not because the attacking species is not powerful enough; indeed we have

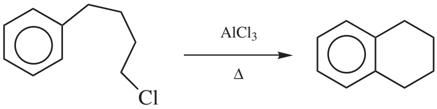
seen (p. 681) that alkyl cations are among the most powerful of electrophiles. The difficulty is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, Friedel–Crafts alkylation can be accomplished.[359] Aromatic nitro compounds can be methylated by a nucleophilic mechanism (**13-17**).

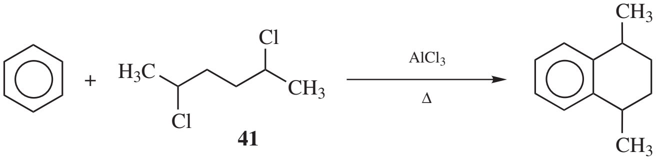
The intermediate for Friedel–Crafts alkylation is a carbocation, and rearrangement to a more stable cation can be quite facile. Therefore, rearrangement of the alkyl substrate occurs frequently and is an important synthetic limitation of Friedel–Crafts alkylation. For example, benzene treated with *n*-propyl bromide gives mostly isopropylbenzene (cumene) and much less *n*-propylbenzene. Rearrangement is usually in the order primary → secondary → tertiary and usually occurs by migration of the smaller group on the adjacent carbon. Therefore, in the absence of special electronic or resonance influences on the migrating group (such as phenyl), H migrates before methyl, which migrates before ethyl, and so on (see discussion of rearrangement mechanisms in Chapter 18). It is therefore not usually possible to put a primary alkyl group (other than methyl[360] and ethyl) onto an aromatic ring by Friedel–Crafts alkylation. Because of these rearrangements, *n*-alkylbenzenes are often prepared by *acylation* (**11-17**), followed by reduction (**19-61**).

An important use of the Friedel–Crafts alkylation reaction is to effect ring closure.[361] The most common method is to heat with aluminum chloride an aromatic compound having a halogen, hydroxy, or alkene group in the proper position, as, for example, in the preparation of tetralin, **40**.



40

Another way of effecting ring closure through Friedel–Crafts alkylation is to use a reagent containing two groups, such as **41**.



41

These reactions are most successful for the preparation of six-membered rings,[362] though five- and Seven-membered rings have also been closed in this

manner. For other Friedel–Crafts ring-closure reactions, see **11-15**, **11-13**, and **11-17**. An interesting variation in this reaction showed that *N*-acyl aniline derivatives, upon treatment with $Et_2P(=O)H$ in water and a water soluble initiator (V-501) led to an intramolecular alkylation reaction to give an amide.[363]

As mentioned above, the electrophile in Friedel–Crafts alkylation is a carbocation, at least in most cases.[364] This is in accord with the knowledge that carbocations rearrange in the direction primary → secondary → tertiary (see Chapter 18). In each case the cation is formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are

From alkyl halides: $RCl + AlCl_3 \longrightarrow R^+ + AlCl_4^-$

From alcohols[365] and Lewis acids: $ROH + AlCl_3 \longrightarrow ROAlCl_2 \longrightarrow R^+ + {}^-OAlCl_2$

From alcohols and proton acids: $ROH + H^+ \longrightarrow ROH_2^+ \longrightarrow R^+ + H_2O$

From alkenes (a supply of protons is usually required): $>C{=}C< + H^+ \longrightarrow H{-}\overset{|}{C}{-}C^{\oplus}$

There is direct evidence, from ir and nmr spectra, that the *tert*-butyl cation is quantitatively formed when *tert*-butyl chloride reacts with $AlCl_3$ in anhydrous liquid HCl.[366] In the case of alkenes, Markovnikov's rule (p. 1019) is followed. Carbocation formation is particularly easy from some reagents, because of the stability of the cations. Triphenylmethyl chloride[367] and 1-chloroadamantane[368] alkylate activated aromatic rings (e.g., phenols, amines) with no catalyst or solvent. Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole, but not benzene.[369] It was noted on p. 476 that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.[370] Lewis acids, such as BF_3[371] or $AlEt_3$,[372] can also be used to alkylation of aromatic rings with alkene units.

There is considerable evidence that many Friedel–Crafts alkylations, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say, $AlCl_4^-$ as the counterion or as a complex. Among the evidence is that methylation of toluene by methyl bromide and methyl iodide gave different ortho/para/meta ratios,[373] although we would expect the same ratios if the same species attacked in each case. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.[374] In these instances a mechanism in which the carbocation is slowly formed and then rapidly attacked by the aromatic ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, are rapidly attacked by the ring (acting as a nucleophile), there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an S_N2 mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a completely S_N2 mechanism requires inversion of configuration. Most investigations of Friedel–Crafts stereochemistry, even where an S_N2 mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion. A few exceptions have been found,[375] most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.[376]

Rearrangement is possible even with a non-carbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of $CH_3{}^{14}CH_2Br$ with $AlBr_3$ in the absence of any aromatic compound gave a mixture of the starting material and $^{14}CH_3CH_2Br$.[377] Similar results were obtained with $PhCH_2{}^{14}CH_2Br$, in which case the rearrangement was so fast that the rate could be measured only below −70°C.[378] Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see **11-33**).[379]

See **14-17** and **14-19** for free-radical alkylation.

A variation of this reaction involves acylation of a β-keto ester, followed by Friedel–Crafts cyclization of the ketone moiety. The product is a coumarin **43**, in what is known as the *Pechmann condensation.*[380] Isolation of esters, such as **42**, is not

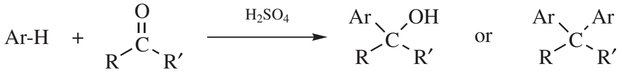
11-12 Hydroxyalkylation or Hydroxyalkyl-de-hydrogenation



When an aldehyde, ketone, or other carbonyl-containing substrate is treated with a protonic or Lewis acid, an oxygen-stabilized cation is generated. In the presence of an aromatic ring, Friedel–Crafts type alkylation occurs. The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.[384] The reaction can be used to prepare alcohols,[385] though more often the alcohol initially produced reacts with another molecule of aromatic compound (**11-11**) to give diarylation. For this the reaction is quite useful, an example being the preparation of DDT, **44**:

44

The diarylation reaction is especially common with phenols (the diaryl product here is called a bisphenol). The reaction is normally carried out in alkaline solution on

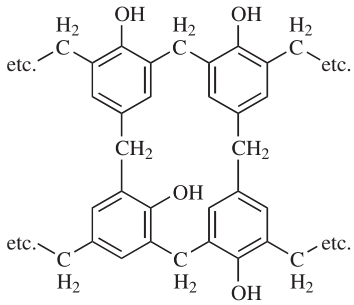
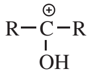
the phenolate ion.[386] Another variation involved Friedel–Crafts coupling of an aldehyde to an activated aromatic compound (an aniline derivative) to give diaryl carbinols that exhibited atropisomerism (see 146).[387] When the reaction was done with a chiral aluminum complex, modest enantioselectivity was observed.

The hydroxymethylation of phenols with formaldehyde is called the *Lederer–Manasse reaction*. This reaction must be carefully controlled,[388] since it is possible for the para and both ortho positions to be substituted and for each of these to be rearylated, so that a polymeric structure **45** is produced. However, such polymers, which are of the Bakelite type (phenol–formaldehyde resins, **45**), are of considerable commercial importance.



45

The attacking species is the carbocation,



formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution.

When an aromatic ring is treated with diethyl oxomalonate, $(EtOOC)_2C{=}O$, the product is an arylmalonic acid derivative $ArC(OH)(COOEt)_2$, which can be converted to an arylmalonic acid, $ArCH(COOEt)_2$.[389] This is therefore a way of applying the malonic ester synthesis (**10-67**) to an aryl group (see also, **13-14**). Of course, the opposite mechanism applies here: The aryl species is the nucleophile.

Two methods, both involving boron-containing reagents, have been devised for the regioselective ortho hydroxymethylation of phenols or aromatic amines.[390]

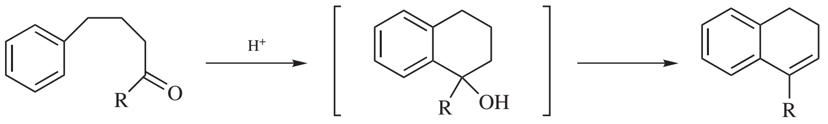
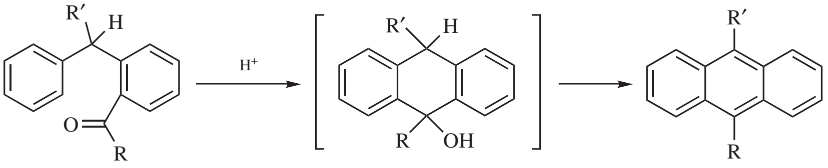
11-13 Cyclodehydration of Carbonyl-Containing Compounds



As described in the previous section (**11-12**), the reaction of carbonyl-containing functional groups with protonic or Lewis acids lead to oxygen-stabilized carbocations. When generated in the presence of an aromatic ring, Friedel–Crafts alkylation occurs to give an alcohol or an alkene, if dehydration occurs under the reaction conditions. When an aromatic compound contains an aldehyde or ketone function in a position suitable for closing a suitably sized ring, treatment with acid results in cyclodehydration. The reaction is a special case of **11-12**, but in this case dehydration almost always takes place to give a double bond conjugated with the aromatic ring.[391] The method is very general and is widely used to close both carbocyclic and heterocyclic rings.[392] Polyphosphoric acid is a common reagent, but other acids have also been used. In a variation known as the *Bradsher reaction*,[393] diarylmethanes containing a carbonyl group in the ortho position can be cyclized to anthracene derivatives, **46**. In this case, 1,4-dehydration takes place, at least formally.



46

An intramolecular cyclization of an aryl ether to the carbonyl of a pendant aryl ketone, on clay with microwave irradiation, led to a benzofuran via Friedel–Crafts cyclization and elimination of water.[394]

The carbonyl unit involved in the cyclization process is not restricted to aldehydes and ketones. The carbonyl of acid derivatives, such as amides can also be utilized. One of the more important cyclodehydration reactions is applied to the formation of heterocyclic systems via cyclization of β-aryl amides, in what is called the *Bischler–Napieralski reaction*.[395] In this reaction amides of the type **47** are

[391]For examples where the hydroxy compound was the principal product (with R = CF_3), see Fung, S.; Abraham, N.A.; Bellini, F.; Sestanj, K. *Can. J. Chem.* ***1983***, *61*, 368; Bonnet-Delpon, D.; Charpentier-Morize, M.; Jacquot, R. *J. Org. Chem.* ***1988***, *53*, 759.

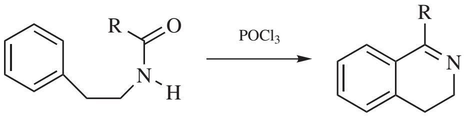
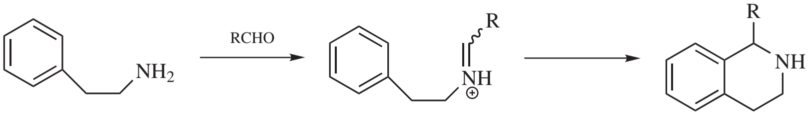
[395]For a review of the mechanism, see Fodor, G.; Nagubandi, S. *Tetrahedron* ***1980***, *36*, 1279.

cyclized with phosphorous oxychloride or other reagents, including polyphosphoric acid, sulfuric acid or phosphorus pentoxide, to give a dihydroisoquinoline, **48**. The Bischler–Napieralski reaction has been done in ionic liquids using $POCl_3$.[396] The reaction has also been done using solid-phase (see p. 416) techniques.[397]



47 **48**

If the starting compound contains a hydroxyl group in the α position, an additional dehydration takes place and the product is an isoquinoline.[398] Higher yields can be obtained if the amide is treated with PCl_5 to give an imino chloride $ArCH_2CH_2N{=}CR{-}Cl$, which is isolated and then cyclized by heating.[399] In this latter case, a nitrilium ion $ArCH_2CH_2{}^{\oplus}N{\equiv}CR$ is an intermediate.



49

Another useful variation is the *Pictet–Spengler isoquinoline synthesis*, also known as the *Pictet–Spengler reaction*.[400] The reactive intermediate is an iminium ion **49** rather than an oxygen-stabilized cation, but attack at the electrophilic carbon of the C=N unit (see **16-31**) leads to an isoquinoline derivative. When a β-arylamine reacts with an aldehyde, the product is an iminium salt, which cyclizes with an aromatic ring to complete the reaction and generate a tetrahydroisoquinoline.[401] A variety of aldehydes can be used, and substitution on the aromatic ring leads to many derivatives. When the reaction is done in the presence of a chiral thiourea catalyst, good enantioselectivity was observed.[402]

Another variation in this basic procedure leads to tetrahydroisoquinolines. When phenethylamine was treated with *N*-hydroxymethylbenzotriazole and then $AlCl_3$ in chloroform, cyclization occurred, and reduction with sodium borohydride gave the 1,2,3,4-tetrahydro-*N*-methylisoquinoline.[403]

[396]The reaction was done in bmim PF_6, 1-butyl-3-methylimidazolium hexafluorophosphate: Judeh, Z.M.A.; Ching, C.B.; Bu, J.; McCluskey, A. *Tetrahedron Lett.* ***2002***, *43*, 5089.

11-14 Haloalkylation or Haloalkyl-de-hydrogenation

$$ArH + HCHO + HCl \xrightarrow{ZnCl_2} ArCH_2Cl$$

When certain aromatic compounds are treated with formaldehyde and HCl, the CH_2Cl group is introduced into the ring in a reaction called *chloromethylation*. The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.[404] The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes. It is greatly hindered by meta-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether ($ClCH_2OMe$), or methoxyacetyl chloride $MeOCH_2COCl$.[405] Zinc chloride is the most common catalyst, but other Friedel–Crafts catalysts are also employed. As with reaction **11-12** and for the same reason, an important side product is the diaryl compound Ar_2CH_2 (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in **11-12**, and then the HCl converts this to the chloroalkyl compound.[406] The acceleration of the reaction by $ZnCl_2$ has been attributed[407] to the raising of the acidity of the medium, causing an increase in the concentration of $HOCH_2^+$ ions.

OS **III**, 195, 197, 468, 557; **IV**, 980.

11-15 Friedel–Crafts Arylation: The Scholl Reaction

De-hydrogen-coupling

$$2\,ArH \xrightarrow[H^+]{AlCl_3} Ar\text{—}Ar + H_2$$

The coupling of two aromatic molecules by treatment with a Lewis acid and a proton acid is called the *Scholl reaction*.[408] Yields are low and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. Because the reaction

[404]For reviews, see Belen'kii, L.I.; Vol'kenshtein, Yu.B.; Karmanova, I.B. *Russ. Chem. Rev.* ***1977***, *46*, 891; Olah, G.A.; Tolgyesi, W.S., in Olah, G.A. *Friedel–Crafts and Related Reactions*, Vol. 2, Wiley, NY, ***1963***, pp. 659–784.

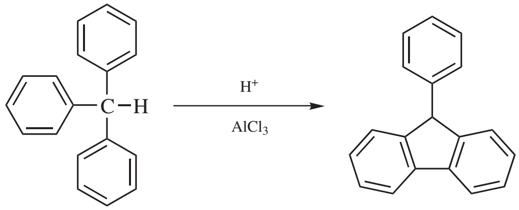
becomes important with large fused-ring systems, ordinary Friedel–Crafts reactions (**11-11**) on these systems are rare. For example, naphthalene gives binaphthyl under Friedel–Crafts conditions. Yields can be increased by the addition of a salt, such as $CuCl_2$ or $FeCl_3$, which acts as an oxidant.[409] Rhodium catalysts have also been used.[410]

Intramolecular Scholl reactions, such as formation of **50** from triphenylmethane,



50

are much more successful than the intermolecular reaction. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of the type **12** (p. 662), which would be the electrophile that attacks the other ring.[411] Sometimes arylations have been accomplished by treating aromatic substrates with particularly active aryl halides, especially fluorides. For free-radical arylations, see reactions **12-15**, **13-26**, **13-27**, **13-10**, **14-17**, and **14-18**.

11-16 Arylation of Aromatic Compounds By Metalated Aryls

$$\text{Ar-M} \xrightarrow{\text{Ar}'\text{-H}} \text{Ar—Ar}'$$

Many metalated aryl compounds are known to couple with aromatic compounds. Aniline derivatives react with $ArPb(OAc)_3$, for example, to give the 2-arylaniline.[412] Phenolic anions also react to form biaryls, with modest enantioselectivity in the presence of brucine.[413]

Phenylboronates [$ArB(OR)_2$] react with electron-deficient aromatic compounds, such as acetophenone, to give the biaryl.[414] Arylboronates also react with π-allyl palladium complexes to form the alkylated aromatic compound.[415]

11-17 Friedel–Crafts Acylation

Acylation or Acyl-de-hydrogenation

$$ArH + RCOCl \xrightarrow{AlCl_3} ArCOR$$

The most important method for the preparation of aryl ketones is known as *Friedel–Crafts acylation*.[416] The reaction is of wide scope. Reagents other than acyl halides can be used,[417] including carboxylic acids,[418] anhydrides, and ketenes. Oxalyl chloride has been used to give diaryl 1,2-diketones.[419] Carboxylic esters usually give alkylation as the predominant product (see **11-11**).[420] *N*-Carbamoyl β-lactams reacted with naphthalene in the presence of trifluoromethanesulfonic acid to give the keto-amide.[421]

The alkyl group (R in RCOCl) may be aryl as well as alkyl. The major disadvantages of Friedel–Crafts alkylation, polyalkylation, and rearrangement of the intermediate carbocation, are not a problem in Friedel–Crafts acylation. Rearrangement of the alkyl group (R in RCOCl) is never found because the intermediate is an acylium ion (an acyl cation, $RC{\equiv}O^+$, see below). Because the RCO group is deactivating, the reaction stops cleanly after one group is introduced. All four acyl halides can be used, though chlorides are most commonly employed. The order of activity is usually, but not always, I > Br > Cl > F.[422] Catalysts are Lewis acids,[423] similar to those in reaction **11-11**, but in acylation a little > than 1 equivalent of catalyst is required per mole of reagent, because the first mole coordinates

with the oxygen of the reagent [as in $R(Cl)C{=}O^{+}\ {}^{-}AlCl_3$].[424] A reusable catalyst [$Ln(OTf)_3$—$LiClO_4$] has been developed as well.[425] HY-Zeolite has also been used to facilitate the reaction with acetic anhydride.[426] A platinum catalyst was used with acetic anhydride,[427] $TiCl_4$ with acetyl chloride[428] or acetyl chloride and zinc powder with microwave irradiation.[429] Friedel–Crafts acylation using a carboxylic acid with a catalyst called Envirocat-EPIC (an acid-treated clay-based material was reported.[430] Friedel–Crafts acylation was reported in an ionic liquid.[431] An interesting acylation reaction was reported that coupled trichlorophenylmethane to benzene, giving benzophenone in the presence of the ionic liquid $AlCl_3$-*n*-BPC.[432] Acylation has been accomplished in carbon disulfide.[433]

Proton acids can be used as catalysts when the reagent is a carboxylic acid. The mixed carboxylic sulfonic anhydrides $RCOOSO_2CF_3$ are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.[434] With active substrates (e.g., aryl ethers, fused-ring systems, thiophenes), Friedel–Crafts acylation can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all.

The reaction is quite successful for many types of substrate, including fused ring systems, which give poor results in **11-11**. Compounds containing ortho–para-directing groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the para products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from *N*- or *O*-acylation; however, *O*-acylated phenols can be converted to *C*-acylated phenols by the Fries rearrangement (**11-27**). Friedel–Crafts acylation is usually prevented by meta-directing groups. Indeed, nitrobenzene is often used as a solvent for the reaction. Many heterocyclic systems, including furans, thiophenes, pyrans, and pyrroles[435]

[424]The crystal structures of several of these complexes have been reported: Rasmussen, S.E.; Broch, N.C. *Acta Chem. Scand.* ***1966***, *20*, 1351; Chevrier, B.; Le Carpentier, J.; Weiss, R. *J. but not pyridines or quinolines, can be acylated in good yield. Initial reaction of indole with Et_2AlCl[436] or $SnCl_4$,[437] followed by acetyl chloride leads to 3-acetylindole. By comparison, the reaction of *N*-acetylindole with acetic anhydride and $AlCl_3$ gave *N*,6-diacetylindole.[438] Acetylation at C-3 was also accomplished with acetyl chloride in the ionic liquid emimcl-$AlCl_3$.[439] Gore, in Ref. 417 (pp. 36–100; with tables, pp. 105–321), presents an extensive summary of the substrates to which this reaction has been applied. Pyridines and quinolines can be also be acylated by a free-radical mechanism (reaction **14-19**).

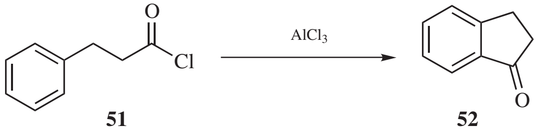
When a mixed-anhydride RCOOCOR′ is the reagent, two products are possible: ArCOR and ArCOR′. Which product predominates depends on two factors. If R contains electron-withdrawing groups, then ArCOR′ is chiefly formed, but if this factor is approximately constant in R and R′, the ketone with the larger R group predominantly forms.[440] This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid HCOOCOR.

An important use of the Friedel–Crafts acylation is to effect ring closure.[441] This can be done if an acyl halide, anhydride, or carboxylic acid[442] group is in the proper position. An example is the conversion of **51** to **52**.



51 **52**

The reaction is used mostly to close six-membered rings, but has also been done for five- and seven-membered rings, which close less readily. Even larger rings can be closed by high-dilution techniques.[443] Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring. Many fused-ring systems are made in this manner. If the bridging group is CO, the product is a quinone.[444] One of the most common catalysts for intramolecular Friedel–Crafts

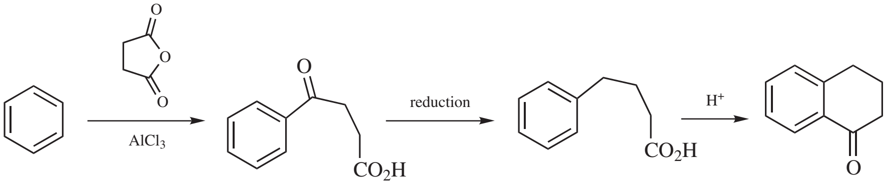
acylation is polyphosphoric acid[445] (because of its high potency), but $AlCl_3$, H_2SO_4, and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

Friedel–Crafts acylation can be carried out with cyclic anhydrides,[446] in which case the product contains a carboxyl group in the side chain (**53**). When succinic anhydride is used, the product is $ArCOCH_2CH_2COOH$. This can be reduced (**19-61**) to $ArCH_2CH_2CH_2COOH$, which can then be cyclized by an internal Friedel–Crafts acylation to give **54**. The total process is called the *Haworth reaction*:[447]

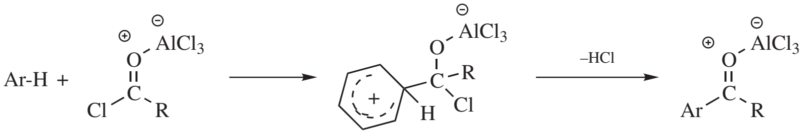


53 **54**

The mechanism of Friedel–Crafts acylation is not completely understood,[448] but at least two mechanisms probably operate, depending on conditions.[449] In most cases the attacking species is the acyl cation, either free or as an ion pair, formed by[450]

$$RCOCl + AlCl_3 \longrightarrow RCO^+ + AlCl_4^-$$

If R is tertiary, RCO^+ may lose CO to give R^+, so that the alkyl arene ArR is often a side product or even the main product. This kind of cleavage is much more likely with relatively unreactive substrates, where the acylium ion has time to break down. For example, pivaloyl chloride Me_3CCOCl gives the normal acyl product with anisole, but the alkyl product Me_3CPh with benzene. In the other mechanism, an acyl cation is not involved, but the 1:1 complex (**55**) attacks directly.[451]



55

[449]For a review of the mechanism, see Taylor, R. *Electrophilic Aromatic Substitution*, Wiley, NY, ***1990***, pp. 222–237.

[450]After 2 min, exchange between PhCOCl and $Al(^{36}Cl)_3$ is complete: Oulevey, G.; Susz, P.B. *Helv. Chim. Acta* ***1964***, *47*, 1828.

[451]For example, see Corriu, R.; Dore, M.; Thomassin, R. *Tetrahedron* ***1971***, *27*, 5601, 5819; Tan, L.K.; Brownstein, S. *J. Org. Chem.* ***1983***, *48*, 302.

Free-ion attack is more likely for sterically hindered R.[452] The ion CH_3CO^+ has been detected (by IR spectroscopy) in the liquid complex between acetyl chloride and aluminum chloride, and in polar solvents, such as nitrobenzene; but in nonpolar solvents, such as chloroform, only the complex and not the free ion is present.[453] In any event, 1 equivalent of catalyst certainly remains complexed to the product at the end of the reaction. When the reaction is performed with $RCO^+SbF_6^-$, no catalyst is required and the free ion[454] (or ion pair) is undoubtedly the attacking entity.[455] The use of $LiClO_4$ on the metal triflate-catalyzed Friedel–Crafts acylation of methoxy-naphthalene derivatives has been examined, and the presence of the lithium salt leads to acylation in the ring containing the methoxy unit, whereas reaction occurs in the other ring in the absence of lithium salts.[456] Note that lithium perchlorate forms a complex with acetic anhydride, which can be used for the Friedel–Crafts acetylation of activated aromatic compounds.[457]

OS **I**, 109, 353, 476, 517; **II**, 3, 8, 15, 81, 156, 169, 304, 520, 569; **III**, 6, 14, 23, 53, 109, 183, 248, 272, 593, 637, 761, 798; **IV**, 8, 34, 88, 898, 900; **V**, 111; **VI**, 34, 618, 625 **X**, 125.

Reaction **11-18** is a direct formylation of the ring.[458] Reaction **11-17** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 h at −60°C,[459] but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.[460] Mixed anhydrides of formic and other acids are known[461] and can be used to formylate amines (see **16-73**) and alcohols, but no formylation takes place when they are applied to aromatic rings. See **13-17** for a nucleophilic method for the formylation of aromatic rings.

A related reaction involves a biaryl, where one ring is a phenol. Treatment with BCl_3 and an $AlCl_3$ catalyst, followed by reaction with CO and $Pd(OAc)_2$, led to

carbonylation and acylation to give the corresponding lactone.[462] Carbonylation of aromatic compounds can lead to aryl ketones. Heating an aromatic compound with $Ru(CO)_{12}$, ethylene and 20 atm of CO gave the corresponding aryl ethyl ketone.[463]

11-18 Formylation

Formylation or Formyl-de-hydrogenation

$$\text{Ar-H} \longrightarrow \text{Ar-CHO}$$

The reaction with disubstituted formamides R_2N—CHO and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier–Haack reaction*,[464] is the most common method for the formylation of aromatic rings.[465] However, it is applicable only to active substrates, such as amines and phenols. An intramolecular version is also known.[466] Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes, ferrocenes). Although *N*-phenyl-*N*-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.[467] Phosgene ($COCl_2$) has been used in place of $POCl_3$. The reaction has also been carried out with other amides to give ketones (actually an example of **11-17**), but not often. The attacking species[468] is **56**,[469] and the mechanism is probably that shown to give **57**, which is unstable and easily hydrolyzes to the product. Either formation of **56** or the reaction of **56** with the substrate can be rate determining, depending on the reactivity of the substrate.[470]

When $(CF_3SO_2)_2O$ was used instead of $POCl_3$, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.[471]

In a related reaction, paraformaldehyde can be used, with $MgCl_2$—NEt_3, to convert phenol to phenol 2-carboxaldehyde.[472] Another variation treated acetanilide with $POCl_3$—DMF and generated 2-chloroquinoline-3-carboxaldehyde.[473] Used in conjunction with conjugated hydroxylamines, a tandem Vilsmeier–Beckman reaction (see **18-17** for the Beckman rearrangement) leads to pyridines (2-chloro-3-carboxaldehyde).[474] A chain-extension variation has been reported in which an aryl alkyl ketone is treated with $POCl_3$/DMF on silica with microwave irradiation to give a conjugated aldehyde, ArC(=O)R → ArC(Cl)=CHCHO.[475]

$$ArH + Zn(CN)_2 \xrightarrow{HCl} ArCH{=}NH_2^+\,Cl^- \xrightarrow{H_2O} ArCHO$$

Formylation with $Zn(CN)_2$ and HCl is called the *Gatterman reaction*.[476] It can be applied to alkylbenzenes, phenols and their ethers, and many heterocyclic compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction the substrate was treated with HCN, HCl, and $ZnCl_2$, but the use of $Zn(CN)_2$ and HCl (HCN and $ZnCl_2$ are generated *in situ*) makes the reaction more convenient to carry out and yields are not diminished. The mechanism of the Gatterman reaction has not been investigated very much, but it is known that an initially formed but not isolated nitrogen-containing product is hydrolyzed to aldehyde. This product is presumed to be $ArCH{=}NH_2^+Cl^-$, as shown. When benzene was treated with NaCN under superacid conditions (F_3CSO_2OH—SbF_5, see p. 236), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was $^+C(H){=}N^+H_2$.[477] The Gatterman reaction may be regarded as a special case of **11-24**.

Another method, formylation with CO and HCl in the presence of $AlCl_3$ and CuCl[478] (the *Gatterman–Koch reaction*), is limited to benzene and alkylbenzenes.[479]

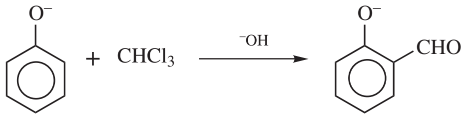
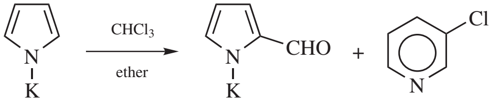
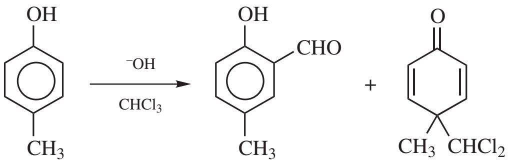
OS **II**, 583; **III**, 549.



In the *Reimer–Tiemann reaction*, aromatic rings are formylated by reaction with chloroform and hydroxide ion.[480] The method is useful only for phenols and certain heterocyclic compounds such as pyrroles and indoles. Unlike the previous formylation methods (**11-18**), this one is conducted in basic solution. Yields are generally low, seldom rising above 50%.[481] The incoming group is directed ortho, unless both ortho positions are filled, in which case the attack is para.[482] Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones. For example, **58** and **60** gave, respectively, **59** and **61** as well as the normal aldehyde products. From the nature of the reagents and



58 **59**



60 **61**

from the kind of abnormal products obtained, it is clear that the reactive entity in this reaction is dichlorocarbene CCl_2.[483] This is known to be produced by treatment of chloroform with bases (p. 521); it is an electrophilic reagent and is known to give ring expansion of aromatic rings (see **15-64**), accounting for products like **58**. The mechanism of the normal reaction is thus something like this.[484]

The formation of **61** in the case of **60** can be explained by attack of some of the CCl_2 ipso to the CH_3 group. Since this position does not contain a hydrogen, normal proton loss cannot take place and the reaction ends when the CCl_2^- moiety acquires a proton.

A method closely related to the Reimer–Tiemann reaction is the *Duff reaction*, in which hexamethylenetetramine $(CH_2)_6N_4$ is used instead of chloroform. This reaction can be applied only to phenols and amines; ortho substitution is generally observed and yields are low. A mechanism[485] has been proposed that involves initial aminoalkylation (**11-22**) to give $ArCH_2NH_2$, followed by dehydrogenation to ArCH=NH and hydrolysis of this to the aldehyde product. When $(CH_2)_6N_4$ is used in conjunction with F_3CCOOH, the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselectively para substitution is found.[486] In this case too an imine seems to be an intermediate.

OS **III**, 463; **IV**, 866

$$ArH + Cl_2CHOMe \xrightarrow{AlCl_3} ArCHO$$

Besides **11-18**, several other formylation methods are known.[487] In one of these, dichloromethyl methyl ether formylates aromatic rings with Friedel–Crafts catalysts.[488] The ArCHClOMe compound is probably an intermediate. Orthoformates have also been used.[489] In another method, aromatic rings are formylated with formyl fluoride HCOF and BF_3.[490] Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl, PhBr, and naphthalene. Phenols can be regioselectively formylated in the ortho position in high yields by treatment with 2 equivalents of paraformaldehyde in aprotic solvents in the presence of $SnCl_4$ and a tertiary amine.[491] Phenols have also been formylated indirectly by conversion to the aryllithium reagent followed by treatment with *N*-formyl piperidine.[492] See also the indirect method mentioned at **11-23**.

Reactions **11-19** and **11-20** are direct carboxylations[493] of aromatic rings.[494]

11-19 Carboxylation With Carbonyl Halides

Carboxylation or **Carboxy-de-hydrogenation**

$$ArH + COCl_2 \xrightarrow{AlCl_3} ArCOOH$$

Phosgene, in the presence of Friedel–Crafts catalysts, can carboxylate the ring. This process is analogous to **11-17**, but the ArCOCl initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the ArCOCl attacks another ring to give a ketone ArCOAr. A number of other reagents have been used to get around this difficulty, among them oxalyl chloride, urea hydrochloride, chloral Cl_3CCHO,[495] carbamoyl chloride H_2NCOCl, and *N*,*N*-diethylcarbamoyl chloride.[496] With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.[497]

Although mechanistically different, other methods are available to convert aromatic compounds to aromatic carboxylic acids. The palladium-catalyzed reaction of aromatic compounds and formic acid leads to benzoic acid derivatives.[498] Diphenyliodonium tetrafluoroborate, $Ph_2I^+BF_4^-$ reacts with CO and In in DMF, with a palladium catalyst, to give benzophenone.[499]

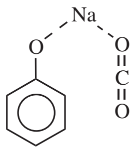
Sodium phenoxides can be carboxylated, mostly in the ortho position, by carbon dioxide (the *Kolbe–Schmitt reaction*). The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants,[500] making the carbon of the CO_2 more positive and putting it in a good



position to attack the ring. Potassium phenoxide, which is less likely to form such a complex,[501] is chiefly attacked in the para position.[502] Carbon tetrachloride can be used instead of CO_2 under Reimer–Tiemann (**11-18**) conditions.

Sodium or potassium phenoxide can be carboxylated regioselectively in the para position in high yield by treatment with sodium or potassium carbonate and carbon monoxide.[503] ^{14}C Labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.[504] The CO is converted to sodium or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with palladium compounds as catalysts.[505] In addition, a palladium-catalyzed reaction has been used directly to prepare acyl fluorides ArH → ArCOF.[506]

An enzymatic carboxylation was reported, in supercritical CO_2 (see p. $$$), in which exposure of pyrrole to *Bacillus megaterium* PYR2910 and $KHCO_3$ gave the potassium salt of pyrrole-2-carboxylic acid.[507]

11-21 Amidation

N-**Alkylcarbamoyl-de-hydrogenation**

$$\text{ArH} + \text{RNCO} \xrightarrow{\text{AlCl}_3} \text{ArCONHR}$$

[500]Hales J.L.; Jones, J.I.; Lindsey, A.S. *J. Chem. Soc.* ***1954***, 3145.

[501]There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO_2: Hirao, I.; Kito, T. *Bull. Chem. Soc. Jpn.* ***1973***, *46*, 3470.

[502]Actually, the reaction seems to be more complicated than this. At least part of the potassium *p*-hydroxybenzoate that forms comes from a rearrangement of initially formed potassium salicylate. Sodium salicylate does not rearrange. See Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 344–348. See also, Ota, K. *Bull. Chem. Soc. Jpn.* ***1974***, *47*, 2343.

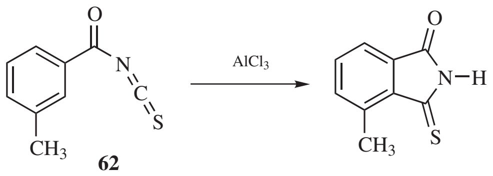
N-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.[508] The R group may be alkyl or aryl, but if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.[509] The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.[510] In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way



of putting a carboxyl group on a ring ortho to one already there (**62** is prepared by treatment of the acyl halide with lead thiocyanate). The reaction gives better yields with substrates of the type $ArCH_2CONCS$, where six-membered rings are formed.

There are interesting transition metal-catalyzed-reactions that lead to aryl amides. The use of $POCl_3$ and DMF, with a palladium catalyst, converts aryl iodides to benzamides.[511] A palladium-catalyzed reaction of aryl halides and formamide leads to benzamide derivatives.[512] Carbonylation is another method that generates amides. When an aryl iodide was treated with a secondary amine and $Mo(CO)_6$, in the presence of 3 equivalents of DBU, 10% $Pd(OAc)_2$, with microwave irradiation at 100°C, the corresponding benzamide was obtained.[513]

OS **V**, 1051; **VI**, 465.

Reactions **11-12–11-23** involve the introduction of a CH_2Z group, where Z is halogen, hydroxyl, amino, or alkylthio. They are all Friedel–Crafts reactions of aldehydes and ketones and, with respect to the carbonyl compound, additions to the C=O double bond. They follow mechanisms discussed in Chapter 16.

11-22 Aminoalkylation and Amidoalkylation

Dialkylaminoalkylation or **Dialkylamino-de-hydrogenation**

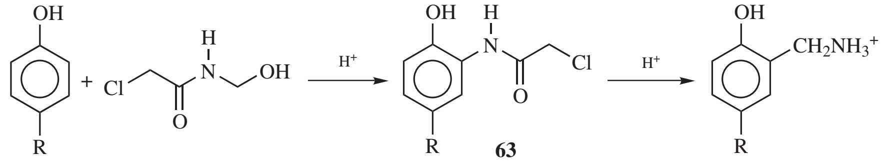
Phenols, secondary and tertiary aromatic amines,[514] pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the Mannich reaction (**16-19**). When phenols and other activated aromatic compounds are treated with *N*-hydroxymethylchloroacetamide, *amidomethylation* takes place[515] to

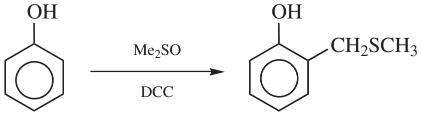


give **63**, which is often hydrolyzed *in situ* to the aminoalkylated product. Other *N*-hydroxyalkyl and *N*-chlorinated compounds have also been used.[374]

OS **I**, 381; **IV**, 626; **V**, 434; **VI**, 965; **VII**, 162.

11-23 Thioalkylation

Alkylthioalkylation or **Alkylthioalkyl-de-hydrogenation**



A methylthiomethyl group can be inserted into the ortho position of phenols by heating with dimethyl sulfoxide and dicyclohexylcarbodiimide (DCC).[516] Other reagents can be used instead of DCC, among them $SOCl_2$,[517] and acetic anhydride.[518] Alternatively, the phenol can be treated with dimethyl sulfide and *N*-chlorosuccinimide, followed by triethylamine.[519] The reaction can be applied to amines (to give *o*-$NH_2C_6H_4CH_2SMe$) by treatment with *t*-BuOCl, Me_2S, and NaOMe in CH_2Cl_2.[520] Aromatic hydrocarbons have been thioalkylated with ethyl α-(chloromethylthio)-acetate $ClCH_2SCH_2COOEt$ (to give $ArCH_2SCH_2CO$-OEt)[521] and with methyl methylsulfinylmethyl sulfide $MeSCH_2SOMe$ or methylthiomethyl *p*-tolyl sulfone $MeSCH_2$-$SO_2C_6H_4Me$ (to give $ArCH_2SMe$),[522] in each case with a Lewis acid catalyst.

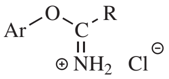
11-24 Acylation with Nitriles: The Hoesch Reaction

Acylation or **Acyl-de-hydrogenation**

$$ArH + RCN \xrightarrow[ZnCl_2]{HCl} ArCOR$$

Friedel–Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben–Hoesch reaction*.[523] In most cases, a Lewis acid is necessary; zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds such as pyrrole, but it can be extended to aromatic amines by the use of BCl_3.[524] Acylation in the case of aniline derivatives is regioselectively ortho. Monohydric phenols, however, generally do not give ketones[525] but are attacked at the oxygen to



An imino ester

produce imino esters. Many nitriles have been used. Even aryl nitriles give good yields if they are first treated with HCl and $ZnCl_2$ and then the substrate added at 0°C.[526] In fact, this procedure increases yields with any nitrile. If thiocyanates RSCN are used, thiol esters ArCOSR can be obtained. The Gatterman reaction (**11-18**) is a special case of the Hoesch synthesis.

The reaction mechanism is complex and not completely settled.[527] The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (**66**). Among the possible attacking species are **64** and **65**. In the second stage, the salts are hydrolyzed to the products, first the iminium salt, and then the ketone. Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of F_3CSO_2OH.[528] The mechanism in this case is different.

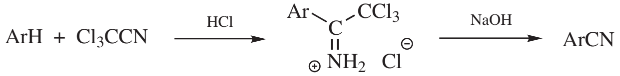
11-25 Cyanation or Cyano-de-hydrogenation



Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile, BrCN, or mercury fulminate Hg(ONC)$_2$.[529] In the case of Cl_3CCN, the actual attacking entity is probably $Cl_3C{-}\overset{\oplus}{C}{=}NH$, formed by addition of a proton to the cyano nitrogen. Secondary aromatic amines ArNHR, as well as phenols, can be cyanated in the ortho position with Cl_3CCN and BCl_3.[530]

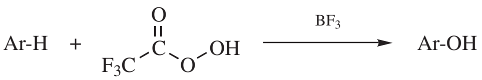
It is noted that aryl triflates are converted to the aryl nitrile by treatment with $Zn(CN)_2$ and a palladium catalyst.[531]

OS **III**, 293.

F. Oxygen Electrophiles

Oxygen electrophiles are very uncommon, since oxygen does not bear a positive charge very well. However, there is one reaction that can be mentioned.

11-26 Hydroxylation or Hydroxy-de-hydrogenation



There have been only a few reports of direct hydroxylation[532] by an electrophilic process (see, however, **14-5**).[533] In general, poor results are obtained, partly because the introduction of an OH group activates the ring to further attack. Quinone formation is common. However, alkyl-substituted benzenes, such as mesitylene or durene can be hydroxylated in good yield with trifluoroperacetic acid and boron trifluoride.[534] In the case of mesitylene, the product (**67**) is not subject to further attack.

In a related procedure, even benzene and substituted benzenes (e.g., PhMe, PhCl, xylenes) can be converted to phenols in good yields with sodium perborate–F_3CSO_2OH.[535] Aromatic amines, *N*-acyl amines, and phenols were hydroxylated with H_2O_2 in SbF_5—HF.[536] Pyridine and quinoline were converted to their 2-acetoxy derivatives in high yields with acetyl hypofluorite AcOF at −75°C.[537]

Another hydroxylation reaction is the *Elbs reaction*.[538] In this method phenols can be oxidized to *p*-diphenols with $K_2S_2O_8$ in alkaline solution.[539] Primary, secondary, or tertiary aromatic amines give predominant or exclusive ortho substitution unless both ortho positions are blocked, in which case para substitution is found. The reaction with amines is called the *Boyland–Sims oxidation*. Yields are low with either phenols or amines, generally <50%. The mechanisms are not clear,[540] but for the Boyland–Sims oxidation there is evidence that the $S_2O_8{}^{2-}$ ion attacks at the ipso position, and then a migration follows.[541]

Electrolysis of benzene, in the presence of trifluoroacetic acid and triethylamine, leads to a 73% yield of phenol.[542]

G. Metal Electrophiles

Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in Chapter 12 (**12-22** and **12-23**).

HYDROGEN AS THE LEAVING GROUP IN REARRANGEMENT REACTIONS

In these reactions, a group is detached from a *side chain* and then attacks the ring, but in other aspects they resemble the reactions already treated in this chapter.[543] Since a group moves from one position to another in a molecule, these are rearrangements. In all these reactions, the question arises as to whether the group that cleaves from a given molecule attacks the same molecule or another one, that is is the reaction intramolecular or intermolecular? For intermolecular reactions the mechanism is the same as ordinary aromatic substitution, but for intramolecular

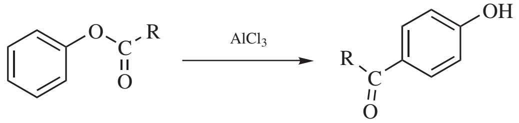
cases the migrating group could never be completely free, or else it would be able to attack another molecule. Since the migrating species in intramolecular rearrangements is thus likely to remain near the atom from which it cleaved, it has been suggested that intramolecular reactions are more likely to lead to ortho products than are the intermolecular type. This characteristic has been used, among others, to help decide whether a given rearrangement is inter- or intramolecular, though there is evidence that at least in some cases, an intermolecular mechanism can still result in a high degree of ortho migration.[544]

The Claisen (**18-33**) and benzidine (**18-36**) rearrangements, which superficially resemble those in this section, have different mechanisms and are treated in Chapter 18.

A. Groups Cleaving from Oxygen

11-27 The Fries Rearrangement

1/*C*-Hydro,5/*O*-acyl-interchange[545]



Phenolic esters can be rearranged by heating with Friedel–Crafts catalysts in a synthetically useful reaction known as the *Fries rearrangement*.[546] Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that either one predominates. The ortho/para ratio is dependent on the temperature, solvent, and amount of catalyst used. Exceptions are known, but low temperatures generally favor the para product and high temperatures the ortho product. The R group may be aliphatic or aromatic. Any meta-directing substituent on the ring interferes with the reactions, as might be expected for a Friedel–Crafts process. In the case of aryl benzoates treated with F_3CSO_2OH, the Fries rearrangement was shown to be reversible and an equilibrium was established.[547] Transition-metal-catalyzed Fries rearrangements have been reported.[548]

[544]See Dawson, I.M.; Hart, L.S.; Littler, J.S. *J. Chem. Soc. Perkin Trans. 2* ***1985***, 1601.

[545]This is the name for the para migration. For the ortho migration, the name is 1/*C*-hydro,3/*O*-acyl-interchange.

[546]For reviews, see Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 72–82, 365–368; Gerecs, A., in Olah, G.A. *Friedel–Crafts and Related Reactions*, Vol. 3, Wiley, NY, ***1964***, pp. 499–533. [548]With **Sc(OTf)$_3$**, see Kobayashi, S.; Moriwaki, M.; Hachiya, I. *Tetrahedron Lett.* ***1996***, *37*, 4183; with $ZrCl_4$ see Harrowven, D.C.; Dainty, R.F. *Tetrahedron Lett.* ***1996***, *37*, 7659; with **Hf(OTf)$_4$** see Kobayashi, S.; Moriwaki, M.; Hachiya, I. *Tetrahedron Lett.* ***1996***, *37*, 2053. Also see Kobayashi, S.; Moriwaki, M.; Hachiya, I. *J. Chem. Soc., Chem. Commun.* ***1995***, 1527.

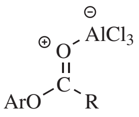
The exact mechanism has still not been completely worked out.[549] Opinions have been expressed that it is completely intermolecular,[550] completely intramolecular,[551] and partially inter- and intramolecular.[552] One way to decide between inter- and intramolecular processes is to run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, though this is not certain, for it may be that the toluene is not attacked because it is less active than the other. A number of such experiments (called *crossover experiments*) have been carried out; sometimes crossover products have been found and sometimes not. As in **11-17**, an initial complex (**68**) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required. In the presence of aluminum chloride, the Fries rearrangement can be induced with microwave irradiation.[553] Simply heating phenyl acetate with microwave irradiation gives the Fries rearrangement.[554] The Fries rearrangement has been carried out in ionic melts.[555]



68

The Fries rearrangement can also be carried out with UV light, in the absence of a catalyst.[556] This reaction, called the *photo-Fries rearrangement*,[557] is predominantly an intramolecular free-radical process. Both ortho and para migration are observed.[558] Unlike the Lewis acid-catalyzed Fries rearrangement, the photo-Fries reaction can be accomplished, though often in low yields, when meta-directing groups are on the ring. The available evidence strongly suggests the following

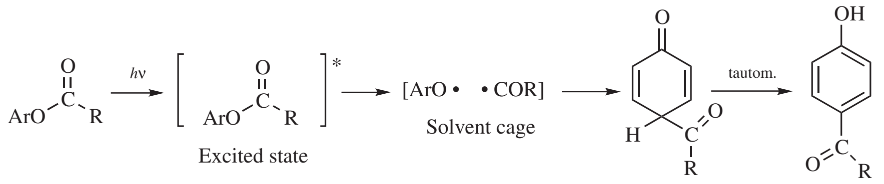
[558]The migration can be made almost entirely ortho by cyclodextrin encapsulation (see p. 129): Syamala, M.S.; Rao, B.N.; Ramamurthy, V. *Tetrahedron* ***1988***, *44*, 7234. See also, Veglia, A.V.; Sanchez, A.M.; de Rossi, R.H. *J. Org. Chem.* ***1990***, *55*, 4083.

mechanism involving formation of the excited state ester followed by dissociation to a radical pair[559] for the photo-Fries rearrangement[560] (illustrated for para attack).



The phenol ArOH is always a side product, resulting from some ArO• that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogens), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.[561] Other evidence[562] for the mechanism is that CIDNP has been observed during the course of the reaction[563] and that the ArO•radical has been detected by flash photolysis[564] and by nanosecond time-resolved Raman spectroscopy.[565]

Treatment of *O*-arylsulfonate esters with $AlCl_3$—$ZnCl_2$, on silica with microwave irradiation, leads to 2-sulfonyl phenols in a thia-Fries rearrangement.[566] A similar reaction was reported with *O*-arylsulfonamides.[567]

OS **II**, 543; **III**, 280, 282.

B. Groups Cleaving from Nitrogen[568]

It has been shown that $PhNH_2D$ rearranges to *o*- and *p*-deuterioaniline.[569] The migration of OH, formally similar to reactions **11-28–11-32**, is a nucleophilic substitution and is treated in Chapter 13 (**13-32**).

[559]Proposed by Kobsa, H. *J. Org. Chem.* ***1962***, *27*, 2293.

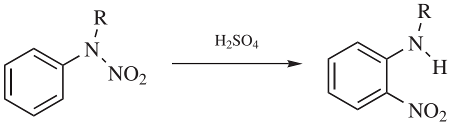
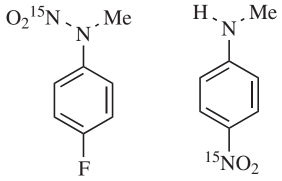
11-28 Migration of the Nitro Group

1/*C*-Hydro,3/*N*-nitro-interchange



N-Nitro aromatic amines rearrange on treatment with acids to *o*- and *p*-nitroamines with the ortho compounds predominating.[570] Aside from this indication of an intramolecular process, there is also the fact that virtually no meta isomer is produced in this reaction,[571] although direct nitration of an aromatic amine generally gives a fair amount of meta product. Thus a mechanism in which NO_2^+ is dissociated from the ring, and then attacks another molecule must be ruled out. Further results indicating an intramolecular process include the observation that rearrangement of several substrates in the presence of $K^{15}NO_3$ gave products containing no ^{15}N,[572] and that rearrangement of a mixture of $PhNH^{15}NO_2$ and unlabeled *p*-$MeC_6H_4NHNO_2$ gave 2-nitro-4-methylaniline containing no ^{15}N.[573] On the other hand, rearrangement of **69** in the presence of



69 **70**

unlabeled $PhNMeNO_2$ gave labeled **70**, which did not arise by displacement of F.[574] The R group may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the ortho position before the group cleaves,[575] and the other involving a cleavage into a

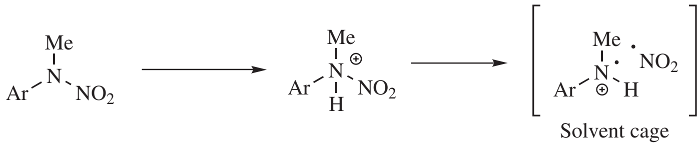
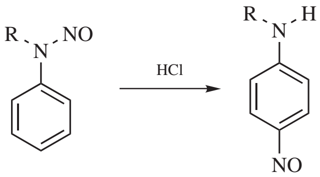
radical and a radical ion held together in a solvent cage.[576] Among the evidence for the latter view[577] are



the effects of substituents on the rate of the reaction,[578] ^{15}N and ^{14}C kinetic isotope effects that show non-concertedness,[579] and the fact that both *N*-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-*N*-methylaniline.[580] These side products are formed when the radicals escape from the solvent cage.

11-29 Migration of the Nitroso Group: The Fischer–Hepp Rearrangement

1/*C*-Hydro-5/*N*-nitroso-interchange



The migration of a nitroso group, formally similar to **11-28**, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct *C*-nitrosation of secondary aromatic amines (see **12-50**). The reaction, known as the *Fischer–Hepp rearrangement*,[581] is brought about by treatment of *N*-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems the para product is usually formed exclusively.[582] The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea[583] shows that it is intramolecular[584] since, if NO^+, NOCl,

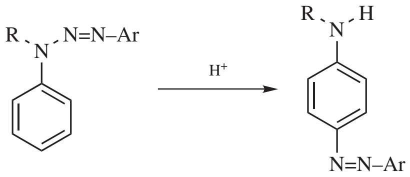
or some similar species were free in the solution, it would be captured by the urea, preventing the rearrangement.

11-30 Migration of an Arylazo Group

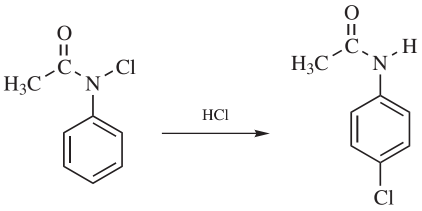
1/*C*-Hydro-5/*N*-arylazo-interchange



Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.[585] These are first diazotized at the amino group (see **11-4**) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the para isomer, unless that position is occupied.

11-31 Migration of Halogen: The Orton Rearrangement

1/*C*-Hydro-5/*N*-halo-interchange



Migration of a halogen from a nitrogen side chain to the ring by treatment with HCl is called the *Orton rearrangement*.[586] The main product is the para isomer, though some ortho product may also be formed. The reaction has been carried out with *N*-chloro- and *N*-bromoamines and less often with *N*-iodo compounds. The amine must be acylated, except that $PhNCl_2$ gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is considerable evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process.[587] First, the HCl reacts with the starting material to give $ArNHCOCH_3$ and Cl_2; then the chlorine halogenates the ring as in **11-10**. Among the evidence is that chlorine has been isolated from the reaction mixture. The Orton rearrangement can also

[585]For a review, see Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 212–221.

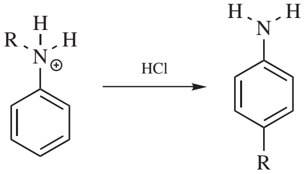
[586]For reviews, see Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 221–230, 362–364: Bieron, J.F.; Dinan, F.J., in Zabicky, J. *The Chemistry of Amides*, Wiley, NY, ***1970***, pp. 263–269.

[587]The reaction has been found to be intramolecular in aprotic solvents: Golding, P.D.; Reddy, S.; Scott, J.M.W.; White, V.A.; Winter, J.G. *Can. J. Chem.* ***1981***, *59*, 839.

be brought about photochemically[588] and by heating in the presence of benzoyl peroxide.[589] These are free-radical processes.

11-32 Migration of an Alkyl Group[590]

1/*C*-Hydro-5/*N*-alkyl-interchange



When HCl salts of arylalkylamines are heated at ~200–300°C, migration occurs in what is called the *Hofmann–Martius reaction.* It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine but also aniline and di- and trimethylanilines.[591] As would be expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an S_N2 reaction:

$$R\overset{\oplus}{N}H_2Ar + Cl^- \longrightarrow RCl + ArNH_2$$

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that Br^-, Cl^-, and I^- gave different ortho/para ratios, which indicates that the halogen is involved in the reaction.[591] Further evidence is that the alkyl halides isolated are not rearranged (as would be expected if they are formed by an S_N2 mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal Friedel–Crafts alkylation process (**11-11**), accounting for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.[592]

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350°C with a metal halide, such as $CoCl_2$, $CdCl_2$, or $ZnCl_2$. When this is done, the reaction is called the *Reilly–Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.[593] The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to alkenes under these conditions.

[588]For example, see Hodges, F.W. *J. Chem. Soc.* ***1933***, 240.

[592]Hart, H.; Kosak, J.R. *J. Org. Chem.* ***1962***, *27*, 116.

[593]For example, see Birchal, J.M.; Clark, M.T.; Goldwhite, H.; Thorpe, D.H. *J. Chem. Soc. Perkin Trans. 1* ***1972***, 2579.

When acylated arylamines are photolyzed, migration of an acyl group takes place[594] in a process that resembles the photo-Fries reaction (**11-27**).

OTHER LEAVING GROUPS

Three types of reactions are considered in this section.

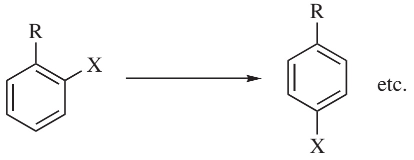
1. Reactions in which hydrogen replaces another leaving group:

$$\mathrm{ArX} + \mathrm{H}^+ \longrightarrow \mathrm{ArH}$$

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

$$\mathrm{ArX} + \mathrm{Y}^+ \longrightarrow \mathrm{ArY}$$

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular:



The three types are not treated separately, but reactions are classified by leaving group.

A. Carbon Leaving Groups

11-33 Reversal of Friedel–Crafts Alkylation

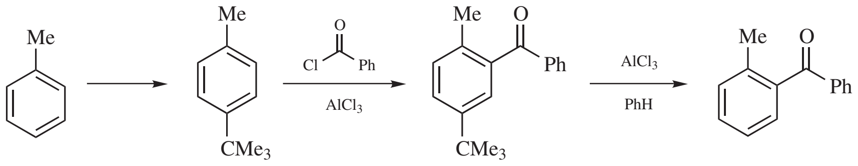
Hydro-de-alkylation or **Dealkylation**

$$\mathrm{ArR} + \mathrm{H}^+ \xrightarrow{\mathrm{AlCl_3}} \mathrm{ArH}$$

Alkyl groups can be cleaved from aromatic rings by treatment with proton and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *tert*-butyl group is occasionally introduced into a ring, used to direct another

[594]For examples see Elad, D.; Rao, D.V.; Stenberg, V.I. *J. Org. Chem.* ***1965***, *30*, 3252; Shizuka, H.; Tanaka, I. *Bull. Chem. Soc. Jpn.* ***1968***, *41*, 2343; ***1969***, *42*, 909; Fischer, M. *Tetrahedron Lett.* ***1968***, 4295; Hageman, H.J. *Recl. Trav. Chim. Pays-Bas* ***1972***, *91*, 1447; Chênevert, R.; Plante, R. *Can. J. Chem.* ***1983***, *61*, 1092; Abdel-Malik, M.M.; de Mayo, P. *Can. J. Chem.* ***1984***, *62*, 1275; Nassetta, M.; de Rossi, R.H.; Cosa, J.J. *Can. J. Chem.* ***1988***, *66*, 2794.

group, and then removed.[595] For example, 4-*tert*-butyltoluene (**71**) reacted with benzoyl chloride and $AlCl_3$ to give the acylated product, and subsequent treatment with $AlCl_3$ led to loss of the *tert*-butyl group to give **72**.[596]



71 **72**

Secondary R groups are harder to cleave, and primary R harder still. Because of this reaction, care must be taken when using Friedel–Crafts catalysts (Lewis or proton acids) on aromatic compounds containing alkyl groups. True cleavage, in which the R becomes an alkene, occurs only at high temperatures, >400°C.[597] At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material. The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is therefore more important than true cleavage. In these reactions, the meta isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5 product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities. Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited: Ethylbenzene treated with HF and BF_3 gave, almost completely, benzene and diethylbenzenes[598] (entirely intermolecular); propylbenzene labeled in the β position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the a position and not at all in the γ position[599] (both intra- and intermolecular); *o*-xylene treated with HBr and $AlBr_3$ gave a mixture of *o*- and *m*-, but no *p*-xylene, while *p*-xylene gave *p*- and *m*-, but no *o*-xylene, and no trimethyl compounds could be isolated in these experiments[600] (exclusively intramolecular rearrangement). Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.[601]

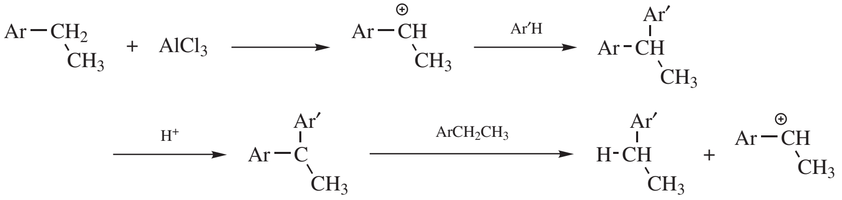
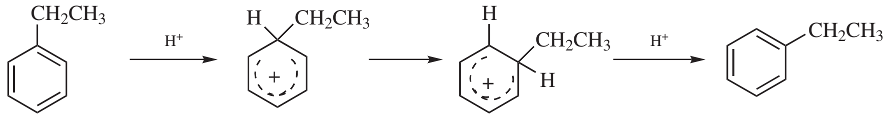
The mechanism[602] of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group. The following mechanism has been proposed for intermolecular rearrangement without the involvement of carbocations that are separated from the ring.[603]



Evidence for this mechanism is that optically active $PhCHDCH_3$ labeled in the ring with ^{14}C and treated with $GaBr_3$ in the presence of benzene gave ethylbenzene containing no deuterium and two deuterium atoms and that the rate of loss of radioactivity was about equal to the rate of loss of optical activity.[603] The mechanism of intramolecular rearrangement is not very clear. 1,2-shifts of this kind have been proposed:[604]



There is evidence from ^{14}C labeling that intramolecular migration occurs only through 1,2-shifts.[605] Any 1,3 or 1,4 migration takes place by a series of two or more 1,2-shifts.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with $AlCl_3$—H_2O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.[606] Alkyl groups have also been replaced by groups other than hydrogen (e.g., nitro groups).

Unlike alkylation, *Friedel–Crafts acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,[607] especially where there are two ortho substituents, for example the

11-34 Decarbonylation of Aromatic Aldehydes

Hydro-de-formylation or **Deformylation**

$$\text{ArCHO} \xrightarrow{H_2SO_4} \text{ArH} + \text{CO}$$

The decarbonylation of aromatic aldehydes with sulfuric acid[609] is the reverse of the *Gatterman–Koch reaction* (**11-18**). It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: the attacking species is H^+ and the leaving group is HCO^+, which can lose a proton to give CO or combine with OH^- from the water solvent to give formic acid.[610] Aromatic aldehydes have also been decarbonylated with basic catalysts.[611] When basic catalysts are used, the mechanism is probably similar to the S_E1 process of **11-35** (see also **14-32**).

11-35 Decarboxylation of Aromatic Acids

Hydro-de-carboxylation or **Decarboxylation**

$$\text{ArCOOH} \xrightarrow[\text{quinoline}]{\text{Cu}} \text{ArH} + CO_2$$

The decarboxylation of aromatic acids is most often carried out by heating with copper and quinoline. However, two other methods can be used with certain substrates. In one method the salt of the acid ($ArCOO^-$) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in ortho and para positions

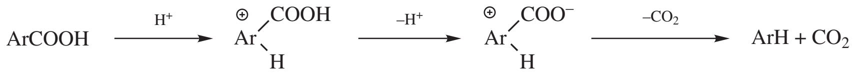
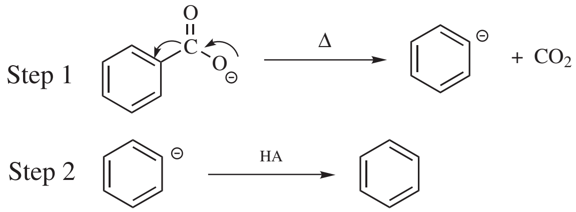
and by the steric effect of groups in the ortho positions; in benzene systems it is generally limited to substrates that contain such groups. In this method, decarboxylation takes place by the arenium ion mechanism,[612] with



H^+ as the electrophile and CO_2 as the leaving group.[613] Evidently, the order of electrofugal ability is $CO_2 > H^+ > COOH^+$, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being of the S_E1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.[614]



Despite its synthetic importance, the mechanism of the copper–quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion.[615] In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous oxide instead of copper, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.[615] It has been shown that cuprous salts of aromatic acids are easily decarboxylated by heating in quinoline[616] and that arylcopper compounds are intermediates that can be isolated in some cases.[617] Metallic silver has been used in place of copper, with higher yields.[618]

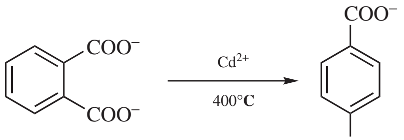
In certain cases, the carboxyl group can be replaced by electrophiles other than hydrogen, for example NO,[618] I,[619] Br,[620] or Hg.[621]

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion (**74**) is produced:[622]



Phthalate ion **74**

In a similar process, potassium benzoate heated with cadmium salts disproportionates to benzene and **74**. The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.[623] An S_E1 mechanism has been suggested.[624] The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.[625]

For aliphatic decarboxylation, see **12-40**.

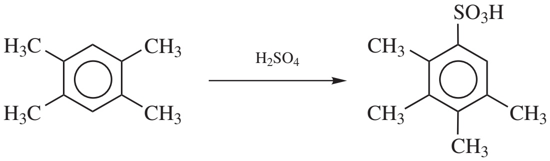
11-36 The Jacobsen Reaction



When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction*, is limited to benzene rings that have at least four substituents, which can be any combination of alkyl and halogen groups, where the alkyl groups can be

ethyl or methyl and the halogen iodo, chloro, or bromo. When isopropyl or *tert*-butyl groups are on the ring, these groups are cleaved to give alkenes. Since a sulfo group can later be removed (**11-38**), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, and so on, indicating an intermolecular process, at least partially.

The mechanism of the Jacobsen reaction is not established,[626] but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.[627] It has been shown by labeling that ethyl groups migrate without internal rearrangement.[628]

Isomerization of alkyl groups in substituted biphenyls has been observed[629] when the medium is a superacid (see p. 236).

B. Oxygen Leaving Groups

11-37 Deoxygenation

$$\text{ArOR} \longrightarrow \text{ArH}$$

In a few cases, it is possible to remove an oxygen substituent directly from the aromatic ring. Treatment of an aryl mesylate (ArOMs) with a nickel catalyst in DMF, for example, leads to the deoxygenated product, Ar—H.[630]

C. Sulfur Leaving Groups

11-38 Desulfonation or Hydro-de-sulfonation

$$\text{ArSO}_3\text{H} \xrightarrow[\text{dil. H}_2\text{SO}_4]{135-200^\circ\text{C}} \text{ArH} + \text{H}_2\text{SO}_4$$

The cleavage of sulfo groups from aromatic rings is the reverse of **11-7**.[631] By the principle of microscopic reversibility, the mechanism is also the reverse.[632] Dilute H_2SO_4 is generally used, as the reversibility of sulfonation decreases with

increasing H_2SO_4 concentration. The reaction permits the sulfo group to be used as a blocking group to direct meta and then to be removed. The sulfo group has also been replaced by nitro and halogen groups. Sulfo groups have also been removed from the ring by heating with an alkaline solution of Raney nickel.[633] In another catalytic process, aromatic sulfonyl bromides or chlorides are converted to aryl bromides or chlorides, respectively, on heating with chlorotris(triphenylphosphine) rhodium(I).[634] This reaction is similar to the decarbonylation of aromatic acyl halides mentioned in **14-32**.

D. Halogen Leaving groups

11-39 Dehalogenation or Hydro-de-halogenation

$$ArX \xrightarrow{AlCl_3} ArH$$

Aryl halides can be dehalogenated by Friedel–Crafts catalysts. Iodine is the most easily cleaved. Dechlorination is seldom performed and defluorination apparently never. The reaction is most successful when a reducing agent, say, Br^- or I^- is present to combine with the I^+ or Br^+ coming off.[635] Except for deiodination, the reaction is seldom used for preparative purposes. Migration of halogen is also found,[636] both intramolecular[637] and intermolecular.[638] The mechanism is probably the reverse of that of **11-10**.[639] Debromination of aromatic rings having two attached amino groups was accomplished by refluxing in aniline containing acetic acid/HBr.[640]

Rearrangement of polyhalobenzenes can also be catalyzed by very strong bases; for example 1,2,4-tribromobenzene is converted to 1,3,5-tribromobenzene by treatment with PhNHK.[641] This reaction, which involves aryl carbanion intermediates (S_E1 mechanism), has been called the *halogen dance*.[642]

Removal of halogen from aromatic rings can also be accomplished by various reducing agents, among them Bu_3SnH,[643] catalytic hydrogenolysis,[644] catalytic transfer hydrogenolysis,[645] $Fe(CO)_5$,[646] Na–Hg in liquid NH_3,[647] $LiAlH_4$,[648] $LiAlH_4$ and a $NbCl_5$ catalyst,[649] $NaBH_4$ and a catalyst,[650] Ni/C with $Me_2NH{\bullet}BH_3$,[651] NaH,[652] HCOOH[653] or aqueous $HCOO^-$[654] with Pd/C, and Raney nickel in alkaline solution,[655] the last method being effective for fluorine, as well as for the other halogens. Carbon monoxide, with potassium tetracarbonylhydridoferrate $KHFe(CO)_4$ as a catalyst, specifically reduces aryl iodides.[656] Polymethylhydrosiloxane (PHMS) and KF, with a palladium catalyst, also reduces aryl iodides.[657] Not all these reagents operate by electrophilic substitution mechanisms. Some are nucleophilic substitutions and some are free-radical processes. Photochemical[658] and electrochemical[659] reduction are also known. Halogen can also be removed from aromatic rings indirectly by conversion to Grignard reagents (**12-38**) followed by hydrolysis (**11-41**).

These reactions are considered along with their aliphatic counterparts at reactions **12-38** and **12-39**.

E. Metal Leaving Groups

11-41 Hydrolysis of Organometallic Compounds

Hydro-de-metallation or **Demetallation**

$$\text{ArM} + \text{H}^+ \longrightarrow \text{ArH} + \text{M}^+$$

Organometallic compounds can be hydrolyzed by acid treatment. For active metals, such as Mg, Li, and so on water is sufficiently acidic. The most important example of this reaction is hydrolysis of Grignard reagents, but M may be many other metals or metalloids. Examples are SiR_3, HgR, Na, and $B(OH)_2$. Since aryl Grignard and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids, such as alkynes.

$$\text{PhMgBr} + \text{H–C}{\equiv}\text{C–H} \longrightarrow \text{H–C}{\equiv}\text{C:}^- \ {}^+\text{MgBr} + \text{PhH}$$

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.[660] Where the bonding is essentially ionic, this is a simple acid–base reaction. For the aliphatic counterpart of this reaction, see reaction **12-24**.

Other reactions of aryl organometallic compounds are treated with their aliphatic analog: reactions **12-25–12-27** and **12-30–12-37**.

[660]For a discussion of the mechanism, see Taylor, R., in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 13, Elsevier, NY, ***1972***, pp. 278–303, 324–349.

CHAPTER 12

Aliphatic, Alkenyl, and Alkynyl Substitution, Electrophilic and Organometallic

In Chapter 11, it was pointed out that the most important leaving groups in electrophilic substitution are those that can best exist with an outer shell that is deficient in a pair of electrons. For aromatic systems, the most common leaving group is the proton. The proton is also a leaving group in aliphatic systems, but the reactivity depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions, for example, α to a carbonyl group, or at an alkynyl position (RC≡CH). Since metallic ions are easily able to bear positive charges, we might expect that organometallic compounds would be especially susceptible to electrophilic substitution, and this is indeed the case.[1] Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C–C bonds; in these reactions there are carbon leaving groups (**12-40–12-46**). A number of electrophilic substitutions at a nitrogen atom are treated at the end of the chapter.

Since a carbanion is what remains when a positive species is removed from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. So is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

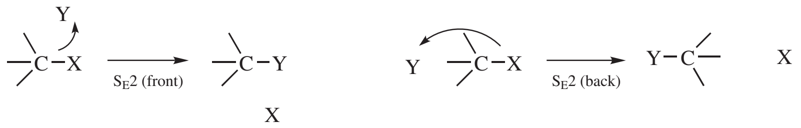
MECHANISMS

For aliphatic electrophilic substitution, we can distinguish at least four possible major mechanisms,[2] which we call S_E1, S_E2 (front), S_E2 (back), and S_Ei. The S_E1 is unimolecular; the other three are bimolecular. It is noted that the term "S_EAr" has been proposed to represent electrophilic aromatic substitution, so that the term "S_E2" refers exclusively to electrophilic substitutions where a steric course is possible.[3] To describe the steric course of an aliphatic substitution reaction, the suffixes "ret" and "inv" were proposed, referring to retention and inversion of configuration, respectively.

BIMOLECULAR MECHANISMS. S_E2 AND S_Ei

The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the S_N2 mechanism in that the new bond forms as the old one breaks. However, in the S_N2 mechanism the incoming group brings with it a pair of electrons, and this orbital can overlap with the central carbon only to the extent that the leaving group takes away its electrons; otherwise the carbon would have more than eight electrons at once in its outer shell. Since electron clouds repel, this means also that the incoming group attacks backside, at a position 180° from the leaving group, resulting in inversion of configuration. When the nucleophilic species attacks (donates electrons to) an electrophile, which brings to the substrate only a vacant orbital, predicting the direction the attack is not as straightforward. We can imagine two main possibilities: delivery of the electrophile to the front, which we call S_E2 (front), and delivery of the electrophile to the rear, which we call S_E2 (back). The possibilities can be pictured (charges not shown):



Both the S_E2 (front) and S_E2 (back) mechanisms are designated D_EA_E in the IUPAC system. With substrates in which we can distinguish the possibility, the former

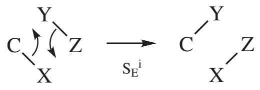
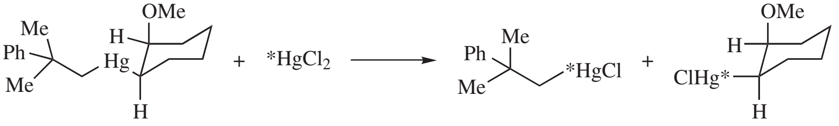
[3]Gawley, R.E. *Tetrahedron Lett.* ***1999***, *40*, 4297.

mechanism should result in retention of configuration and the latter in inversion. The reaction of allylsilanes with adamantyl chloride and $TiCl_4$, for example, gives primarily the antiproduct via a S_E2' reaction.[4] When the electrophile reacts from the front, there is a third possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new C–Y bond is formed:



This mechanism, which we call the S_Ei mechanism[5] (IUPAC designation: *cyclo*-$D_EA_ED_nA_n$), also results in retention of configuration.[6] Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

It is evident that these three mechanisms are not easy to distinguish. All three give second-order kinetics, and two result in retention of configuration.[7] In fact, although much work has been done on this question, there are few cases in which we can unequivocally say that one of these three and not another is actually



1 **2**

taking place. Clearly, a study of the stereochemistry can distinguish between S_E2 (back) on the one hand and S_E2 (front) or S_Ei on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an S_E2 (front) or S_Ei mechanism. For example, when *cis*-**1** was treated with labeled mercuric chloride, the **2** produced was 100% cis. The bond between the mercury and the ring must have been broken (as well as the other Hg–C bond), since each of the products contained about half of the labeled mercury.[8] Another indication of frontside attack is that second-order

[4]Buckle, M.J.C.; Fleming, I.; Gil, S. *Tetrahedron Lett.* ***1992***, *33*, 4479.

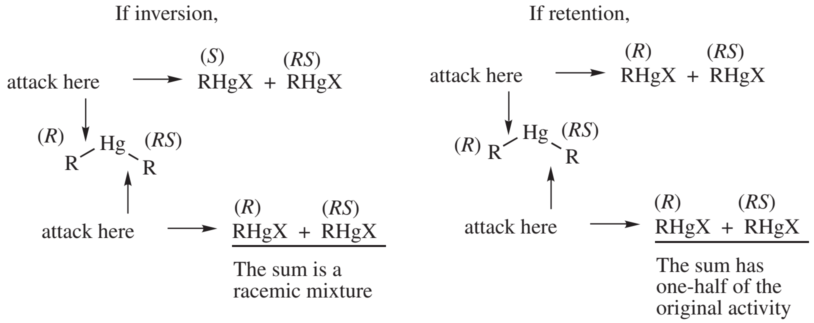
[5]The names for these mechanisms vary throughout the literature. For example, the S_Ei mechanism has also been called the S_F2, the S_E2 (closed), and the S_E2 (cyclic) mechanism. The original designations, S_E1, S_E2, and so on, were devised by the Hughes–Ingold school.

[6]It has been contended that the S_Ei mechanism violates the principle of conservation of orbital symmetry (p. 1208), and that the S_E2 (back) mechanism partially violates it: Slack, D.A.; Baird, M.C. *J. Am. Chem. Soc.* ***1976***, *98*, 5539.

[7]For a review of the stereochemistry of reactions in which a carbon-transition-metal σ bond is formed or broken, see Flood, T.C. *Top. Stereochem.* ***1981***, *12*, 37. See also Jensen, F.R.; Davis, D.D. *J. Am. Chem. Soc.* ***1971***, *93*, 4048.

[8]Winstein, S.; Traylor, T.G.; Garner, C.S. *J. Am. Chem. Soc.* ***1955***, *77*, 3741.

electrophilic substitutions proceed very easily at *bridgehead* carbons (see p. 429).[9] Still another indication is the behavior of neopentyl as a substrate. S_N2 reactions at neopentyl are extremely slow (p. 479), because attack from the rear is blocked and the transition state for the reaction lies very high in energy. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl[10] is further evidence for frontside attack. One final elegant experiment may be noted.



The compound di-*sec*-butylmercury was prepared with one *sec*-butyl group optically active and the other racemic.[11] This was accomplished by treatment of optically active *sec*-butylmercuric bromide with racemic *sec*-butylmagnesium bromide. The di-*sec*-butyl compound was then treated with mercuric bromide to give 2 eqiuivalents of *sec*-butylmercuric bromide. The steric course of the reaction could then be predicted by the following analysis, assuming that the bonds between the mercury and each carbon have a 50% chance of breaking. The original activity referred to is the activity of the optically active *sec*-butylmercuric bromide used to make the dialkyl compound. The actual result was that, under several different sets of conditions, the product had one-half of the original activity, demonstrating retention of configuration.

However, inversion of configuration has been found in certain cases, demonstrating that the S_E2 (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (**12-40**) gives inverted *sec*-butyl bromide.[12] A number of other organometallic compounds have also been shown to give inversion when treated with halogens,[13] although others do not.[14] So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside

$$sec\text{-BuSnR}_3 \quad + \quad Br_2 \longrightarrow sec\text{-BuBr} \qquad R = \text{neopentyl}$$

attack exist,[15] but have escaped detection because of the difficulty in preparing compounds with a configurationally stable carbon–metal bond. Compounds that are chiral because of a stereogenic carbon at which a carbon–metal bond is located[16] are often difficult to resolve and once resolved are often easily racemized. The resolution has been accomplished most often with organomercury compounds,[17] and most stereochemical investigations have therefore been made with these substrates. Only a few optically active Grignard reagents have been prepared[18] (i.e., in which the only stereogenic center is the carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C–Mg bond has not often been determined. However, in one such case, the reaction of both the exo and endo isomers of the 2-norbornyl Grignard reagent with $HgBr_2$ (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.[19] It is likely that inversion takes place only when steric hindrance

[12]Jensen, F.R.; Davis, D.D. *J. Am. Chem. Soc.* ***1971***, *93*, 4048. For a review of the stereochemistry of S_E2 reactions with organotin substrates, see Fukuto, J.M.; Jensen, F.R. *Acc. Chem. Res.* ***1983***, *16*, 177.

[13]For example, See Applequist, D.E.; Chmurny, G.N. *J. Am. Chem. Soc.* ***1967***, *89*, 875; Glaze, W.H.; Selman, C.M.; Ball Jr., A.L.; Bray, L.E. *J. Org. Chem.* ***1969***, *34*, 641; Brown, H.C.; Lane, C.F. *Chem. Commun.* ***1971***, 521; Jensen, F.R.; Madan, V.; Buchanan, D.H. *J. Am. Chem. Soc.* ***1971***, *93*, 5283; Espenson, J.H.; Williams, D.A. *J. Am. Chem. Soc.* ***1974***, *96*, 1008; Bock, P.L.; Boschetto, D.J.; Rasmussen, J.R.; Demers, J.P.; Whitesides, G.M. *J. Am. Chem. [14]See, for example, Rahm, A.; Pereyre, M. *J. Am. Chem. Soc.* ***1977***, *99*, 1672; McGahey, L.F.; Jensen, F.R. *J. Am. Chem. Soc.* ***1979***, *101*, 4397. Electrophilic bromination of certain organotin compounds was found to proceed with inversion favored for equatorial and retention for axial C–Sn bonds: Olszowy, H.A.; Kitching, W. *Organometallics* ***1984***, *3*, 1676. For a similar result, see Rahm, A.; Grimeau, J.; Pereyre, M. *J. Organomet. Chem.* ***1985***, *286*, 305.

[15]Cases of inversion involving replacement of a metal by a metal have been reported. See Tada, M.; Ogawa, H. *Tetrahedron Lett.* ***1973***, 2639; Fritz, H.L.; Espenson, J.H.; Williams, D.A.; Molander, G.A. *J. Am. Chem. Soc.* ***1974***, *96*, 2378; Gielen, M.; Fosty, R. *Bull. Soc. Chim. Belg.* ***1974***, *83*, 333; Bergbreiter, D.E.; Rainville, D.P. *J. Organomet. Chem.* ***1976***, *121*, 19.

[16]For a monograph, see Sokolov, V.I. *Chirality and Optical Activity in Organometallic Compounds*, Gordon and Breach, NY, ***1990***.

[17]Organomercury compounds were first resolved by three groups: Jensen, F.R.; Whipple, L.D.; Wedegaertner, D.K.; Landgrebe, J.A. *J. Am. Chem. Soc.* ***1959***, *81*, 1262; Charman, H.B.; Hughes, E.D.; Ingold, C.K. *J. Chem. Soc.* ***1959***, 2523, 2530; Reutov, O.A.; Uglova, E.V. *Bull. Acad. Sci. USSR Div. Chem. Sci.* ***1959***, 735.

[18]This was done first by Walborsky, H.M.; Young, A.E. *J. Am. Chem. Soc.* ***1964***, *86*, 3288.

[19]Jensen, F.R.; Nakamaye, K.L. *J. Am. Chem. Soc.* ***1966***, *88*, 3437.

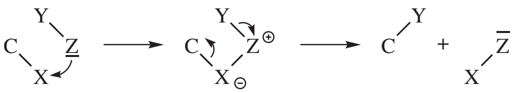
prevents reaction on the frontside and when the electrophile does not carry a Z group (p. 754).

The S_E2 (back) mechanism can therefore be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the S_E2 (front) and the S_Ei mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the S_Ei mechanism on the one hand and the S_E2 pathways on the other involves the study of salt effects on the rate. It may be recalled (p. 501) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the S_Ei mechanism would be less influenced by salt effects than would either of the S_E2 mechanisms. On this basis, Abraham and co-workers[20] concluded that the reactions $R_4Sn + HgX_2 \rightarrow RHgX + R_3SnX$ ($X = Cl$ or I) take place by S_E2 and not by S_Ei mechanisms. Similar investigations involve changes in solvent polarity (see also, p. 765).[21] In the case of the reaction

$$sec\text{-BuSnR}_2\text{R}' + \text{Br}_2 \longrightarrow sec\text{-BuBr}$$

(where $R = R' = i$Pr and $R = i$Pr, $R' =$ neopentyl), the use of polar solvents gave predominant inversion, while nonpolar solvents gave predominant retention.[22]

On the basis of evidence from reactivity studies, it has been suggested[23] that a variation of the S_Ei mechanism is possible in which the group Z becomes attached to X before the latter becomes detached:



This process has been called the S_EC[22] or S_E2 (co-ord)[24] mechanism (IUPAC designation $A_n + cyclo\text{-}D_EA_ED_n$).

It has been shown that in certain cases (e.g., $Me_4Sn + I_2$) the reactants in an S_E2 reaction, when mixed, give rise to an immediate charge-transfer spectrum (p. 115), showing that an electron donor–acceptor (EDA) complex has been formed.[25] In these cases it is likely that the EDA complex is an intermediate in the reaction.

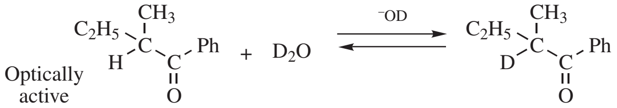
THE S_E1 MECHANISM

The S_E1 mechanism is analogous to the S_N1. It involves two steps: a slow ionization and a fast combination.

$$\text{Step 1} \quad R\text{—}X \xrightarrow{\text{slow}} R^- + X^+$$

$$\text{Step 2} \quad R^- + Y^+ \longrightarrow R\text{—}Y$$

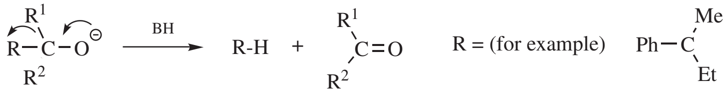
The IUPAC designation is $D_E + A_E$. First-order kinetics are predicted and many such examples have been found. Other evidence for the S_E1 mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction



the rate of deuterium exchange was the same as the rate of racemization[26] and there was an isotope effect.[27]

The S_N1 reactions do not proceed at strained bridgehead carbons (e.g., in [2.2.1] bicyclic systems, p. 435) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar, and S_E1 reactions readily occur with this type of substrate. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the S_E1 reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure, that is, if there is pyramidal inversion as with amines (p. 142). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (p. 258). For simple alkyl carbanions, the main approach to determining structure has been to study the stereochemistry of S_E1 reactions rather than the other way around. Racemization is almost always observed, but whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either, case racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

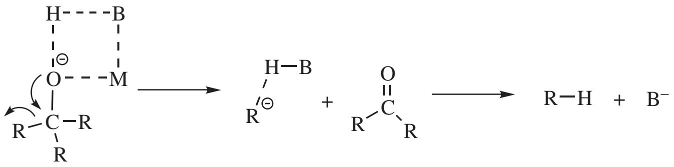
However, even planar carbanions need not give racemization. Cram found that retention and even inversion can occur in the alkoxide (see **3**) cleavage reaction (**12-41**):



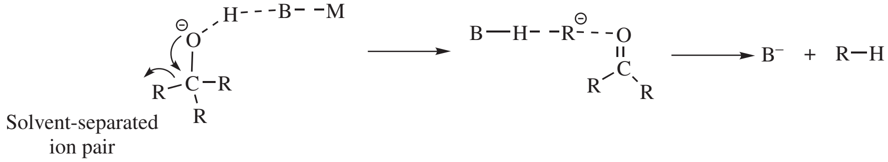
3

[26]Hsu, S.K.; Ingold, C.K.; Wilson, C.L. *J. Chem. Soc.* ***1938***, 78.
[27]Wilson, C.L. *J. Chem. Soc.* ***1936***, 1550.

which is a first-order S_E1 reaction involving resonance-stabilized planar carbanions (here designated R^-).[28] By changing the solvent Cram was able to produce products ranging from 99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free but is solvated. In nondissociating, nonpolar solvents, such as benzene or dioxane, the alkoxide ion exists as an ion pair, solvated by the solvent BH:

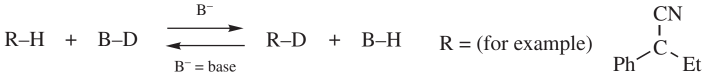


In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. As is easily seen, this solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents, such as diethylene glycol, a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:



When C–H bond formation occurs, the result is inversion. Racemization results in polar aprotic solvents, such as DMSO. In these solvents, the carbanions are relatively long lived (because the solvent has no proton to donate) and symmetrically solvated.

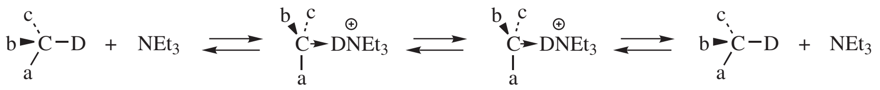
Similar behavior was found for carbanions generated by base-catalyzed hydrogen exchange (reaction **12-1**):[29]



[28]See Cram, D.J.; Langemann, A.; Allinger, J.; Kopecky, K.R. *J. Am. Chem. Soc.* ***1959***, *81*, 5740; Hoffman, T.D.; Cram, D.J. *J. Am. Chem. Soc.* ***1969***, *91*, 1009. For a discussion, see Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, ***1965***, pp. 138–158.

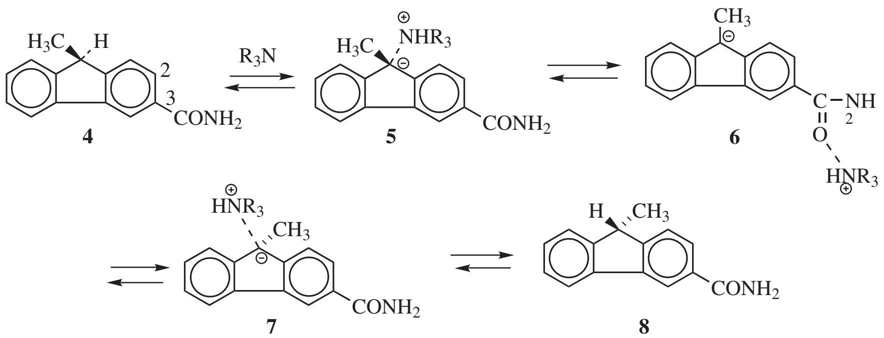
[29]See Roitman, J.N.; Cram, D.J. *J. Am. Chem. Soc.* ***1971***, *93*, 2225, 2231 and references cited therein; Cram, J.M.; Cram, D.J. *Intra-Sci. Chem. Rep.* ***1973***, *7(3)*, 1. For a discussion, see Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, ***1965***, pp. 85–105.

In this case, information was obtained from measurement of the ratio of k_e (rate constant for isotopic exchange) to k_a (rate constant for racemization). A k_e/k_a ratio substantially >1 means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A k_e/k_a ratio of ~1 indicates racemization and a ratio of $\frac{1}{2}$ corresponds to inversion (see p. 430). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton-exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the k_e/k_a ratio was found to be *less* than 0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton:



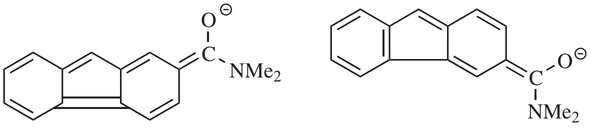
Thus, inversion (and hence racemization, which is produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion*.

The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (**4**) with Pr_3N in *t*-BuOH, it has been proposed that the amine removes



a proton from the 9 position of **4** and conducts the proton out to the C=O oxygen (**6**), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of **7** gives the inverted product **8**. Of course, **6** could also go back to **4**, but a molecule that undergoes the total process **4** → **5** → **6** → **7** → **8** has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted*

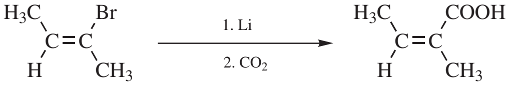
tour mechanism,[30] is that the 12-carboxamido isomer of **4** does not give isoracemization. In this case, the negative charge on the oxygen atom in the anion corresponding to **6** is less, because a canonical form in which oxygen acquires a full negative charge (**9**) results in disruption of the aromatic sextet in both



9 **10**

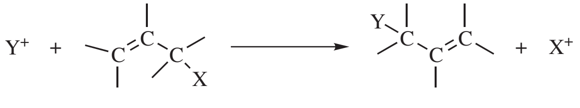
benzene rings (cf. **10** where one benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.[31]

It is known that vinylic carbanions *can* maintain configuration, so that S_E1 mechanisms should produce retention there. This has been found to be the case. For example, *trans*-2-bromo-2-butene was converted to 64–74% angelic acid:[32]



Only ~5% of the cis isomer, tiglic acid, was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (p. 258) and S_E1 reactions involving them proceed with retention of configuration.

Electrophilic Substitution Accompanied by Double-Bond Shifts



11 **12**

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged (**11** → **12**). This type of process is analogous to the nucleophilic

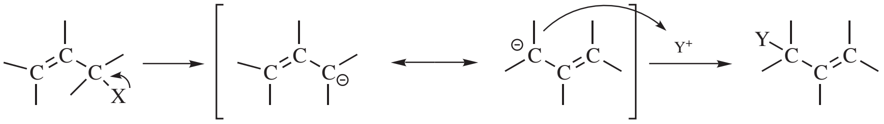
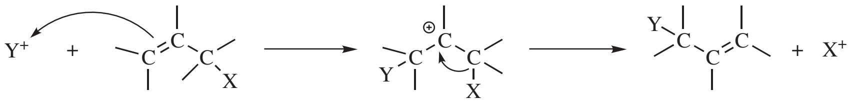
[31] Almy, J.; Hoffman, D.H.; Chu, K.C.; Cram, D.J. *J. Am. Chem. Soc.* ***1973***, *95*, 1185.

[32] Dreiding, A.S.; Pratt, R.J. *J. Am. Chem. Soc.* ***1954***, *76*, 1902. See also Walborsky, H.M.; Turner, L.M. *J. Am. Chem. Soc.* ***1972***, *94*, 2273.

allylic rearrangements discussed in Chapter 10 (p. 468). There are two principal pathways. The first of these is analogous to the S_E1 mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, which then attacks the electrophile.

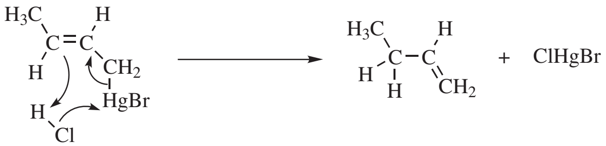


In the other pathway, the Y group is first attacked by the π-bond, giving a carbocation, which then loses X with formation of the alkene unit.

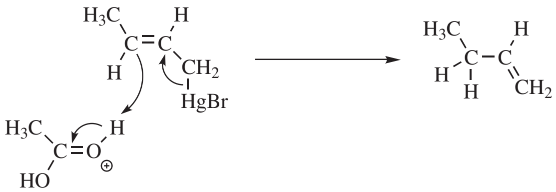


These mechanisms are more fully discussed under reaction **12-2**.

Most electrophilic allylic rearrangements involve loss of hydrogen, but they have also been observed with metallic leaving groups.[33] Sleezer, Winstein, and Young found that crotylmercuric bromide reacted with HCl ~10^7 times faster than *n*-butylmercuric bromide and the product was >99% 1-butene.[34] These facts point to an S_Ei' mechanism (IUPAC designation *cyclo*-1/3/$D_EA_ED_nA_n$):



The reaction of the same compound with acetic acid-perchloric acid seems to proceed by an S_E2' mechanism (IUPAC designation 1/3/D_EA_E):[34]



[33]For a review of reactions of allylic organometallic compounds, see Courtois, G.; Miginiac, L. *J. Organomet. Chem.* ***1974***, *69*, 1.

[34]Sleezer, P.D.; Winstein, S.; Young, W.G. *J. Am. Chem. Soc.* ***1963***, *85*, 1890. See also, Cunningham, I.M.; Overton, K.H. *J. Chem. Soc. Perkin Trans. 1* ***1975***, 2140; Kashin, A.N.; Bakunin, V.N.; Khutoryanskii, V.A.; Beletskaya, I.P.; Reutov, O.A. *J. Org. Chem. USSR* ***1979***, *15*, 12; *J. Organomet. Chem.* ***1979***, *171*, 309.

The geometry of electrophilic allylic rearrangement has not been studied very much (cf. the nucleophilic case, p. 471), but in most cases the rearrangement takes place with anti stereoselectivity,[35] although syn stereoselectivity has also been demonstrated.[36] In one case, use of the electrophile H^+ and the leaving group $SnMe_3$ gave both syn and anti stereoselectivity, depending on whether the substrate was cis or trans.[37]

Other Mechanisms

Addition–elimination (**12-16**) and cyclic mechanisms (**12-40**) are also known.

Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions, and the exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to permit us to decide which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

REACTIVITY

Only a small amount of work has been done in this area, compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Only a few conclusions, most of them sketchy or tentative, can be drawn.[38]

1. *Effect of Substrate*. For S_E1 reactions electron-donating groups decrease rates and electron-withdrawing groups increase them. This is as would be expected from a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the S_E2 (back) mechanism, Jensen and Davis[12] showed that the reactivity of alkyl groups is similar to that for the S_N2 mechanism (i.e., Me > Et > Pr > *i*Pr > neopentyl), as would be expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the S_E2 (back) mechanism in cases where

TABLE 12.1. Relative Rates of the Reaction of RHgBr with Br_2 and Br^- [41]

R	Relative Rate	R	Relative Rate
Me	1	Et	10.8
Et	10.8	*i*Bu	1.24
*i*Pr	780	Neopentyl	0.173
t-Bu	3370		

stereochemical investigation is not feasible.[39] For S_E2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.[40] One such study, which examined the reaction $RHgBr + Br_2 \rightarrow RBr$ catalyzed by Br^-, gave the results shown in Table 12.1.[41] As can be seen, a branching increased the rates, while β branching decreased them. Sayre and Jensen attributed the decreased rates to steric hindrance, although attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which stabilized the electron-deficient transition state.[42] Of course, steric hindrance should also be present with the a branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is a rather large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed[43] to an S_E2 mechanism involving ion pairs, analogous to Sneen's ion-pair mechanism for nucleophilic substitution (p. 441). Solvolysis of 2-bromo-1,1,1-trifluoro-2-(*p*-methoxyphenyl)ethane in water proceeds via a free carbocation intermediate, but ion pairing influences the reaction in the presence of bromide ion.[44]

2. *Effect of Leaving Group.* For both S_E1 and second-order mechanisms, the more polar the C–X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence >1, the nature of the other group or groups attached to the metal thus has an effect on the reaction.

[39]Another method involves measurement of the susceptibility of the rate to increased pressure: See Isaacs, N.S.; Javaid, K. *Tetrahedron Lett.* ***1977***, 3073; Isaacs, N.S.; Laila, A.H. *Tetrahedron Lett.* ***1984***, *25*, 2407.

[40]For some of these, see Abraham, M.H.; Grellier, P.L. *J. Chem. Soc. Perkin Trans. 2* ***1973***, 1132; Dessy, R.E.; Reynolds, G.F.; Kim, J. *J. Am. Chem. Soc.* ***1959***, *81*, 2683; Minato, H.; Ware, J.C.; Traylor, T.G. *J. Am. Chem. Soc.* ***1963***, *85*, 3024; Boué, S.; Gielen, M.; Nasielski, J. *J. Organomet. Chem.* ***1967***, *9*, 443; Abraham, M.H.; Broadhurst, A.T.; Clark, I.D.; Koenigsberger, R.U.; Dadjour, D.F. *J. Organomet. Chem.* ***1981***, *209*, 37.

[41]Sayre, L.M.; Jensen, F.R. *J. Am. Chem. Soc.* ***1979***, *101*, 6001.

[42]A similar conclusion, that steric and electronic effects are both present, was reached for a different system by Nugent, W.A.; Kochi, J.K. *J. Am. Chem. Soc.* ***1976***, *98*, 5979.

[43]Reutov, O.A. *J. Organomet. Chem.* ***1983***, *250*, 145. See also, Butin, K.P.; Magdesieva, T.V. *J. Organomet. Chem.* ***1985***, *292*, 47; Beletskaya, I.P. *Sov. Sci. Rev. Sect. B* ***1979***, *1*, 119.

[44]Richard, J.P. *J. Org. Chem.* ***1992***, *57*, 625.

For example, consider a series of organomercurials RHgW. Because a more electronegative W decreases the polarity of the C–Hg bond and furthermore results in a less stable HgW^+, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, HgR′ (from RHgR′) is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg-*t*-Bu > Hg-*i*Pr > HgEt > HgMe, reported for acetolysis of R_2Hg,[42] since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups, S_E1 mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the results so far reported have been just about the reverse of this. For carbon leaving groups the mechanism is usually S_E1, while for metallic leaving groups the mechanism is almost always S_E2 or S_Ei. A number of reports of S_E1 reactions with metallic leaving groups have appeared,[45] but the mechanism is not easy to prove and many of these reports have been challenged.[46] Reutov and co-workers[45] have expressed the view that in such reactions a nucleophile (which may be the solvent) must assist in the removal of the electrofuge and refer to such processes as $S_E1(N)$ reactions.

3. *Effect of Solvent.*[47] In addition to the solvent effects on certain S_E1 reactions, mentioned earlier (p. 758), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (p. 501), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case S_E1, in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (p. 758), the solvent can also exert an influence between the S_E2 (front or back) and S_Ei mechanisms in that the rates of S_E2 mechanisms should be increased by an increase in solvent polarity, while S_Ei mechanisms are much less affected.

REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

Hydrogen as Leaving Group

A. Hydrogen as the Electrophile

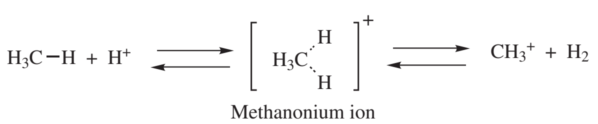
12-1 Hydrogen Exchange

Deuterio-de-hydrogenation or **Deuteriation**

$$R{-}H + D^+ \rightleftharpoons R{-}D + H^+$$

Hydrogen exchange can be accomplished by treatment with acids or bases. As with **11-1**, the exchange reaction is mostly used to study mechanistic questions, such as relative acidities, but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids, such as H_2SO_4 are used, only fairly acidic protons *n* carbon exchange, for example, acetylenic and allylic. However, primary, secondary, and tertiary hydrogens of alkanes can be exchanged by treatment with superacids (p. 236).[48] The order of hydrogen reactivity is tertiary > secondary > primary. Where C–C bonds are present, they may be cleaved also (**12-47**). The mechanism of the exchange (illustrated for methane) has been formulated as involving attack of H^+ on the C–H bond to give the pentavalent methanonium ion that loses H_2 to give a tervalent



carbocation.[49] The methanonium ion $CH_5{}^+$ has a three-center, two-electron bond.[50] It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion $CH_5{}^+$ has been detected in the mass spectrum.[51] The IR spectrum of the ethanonium ion $C_2H_7{}^+$ has been measured in the gas phase.[52] Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogens, leaving the $CH_3{}^+$ free (the forward reaction), or they can unite the CH_3 with either of the two hydrogens, leaving the other hydrogen as a free H^+ ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to CH_4 by the route shown (leading to H^+ exchange) or it can react with additional CH_4 molecules (**12-20**) to eventually yield the *tert*-butyl cation, which is stable in these superacid solutions. Hydride ion can also be removed from alkanes (producing tervalent carbocations) by treatment with pure SbF_5 in the absence of any source of H^+.[53] Complete or almost complete perdeuteriation of cyclic alkenes has been achieved by treatment with dilute DCl/D_2O in sealed Pyrex tubes at 165–280°C.[54]

Exchange with bases involves an S_E1 mechanism.

$$\text{Step 1} \quad RH + B^- \longrightarrow R^- + BH$$

$$\text{Step 2} \quad R^- + BD \longrightarrow RD + B^-$$

Of course, such exchange is most successful for relatively acidic protons, such as those a to a carbonyl group, but even weakly acidic protons can exchange with bases if the bases are strong enough (see p. 251).

Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated treatment with D_2 gas and a catalyst, such as Rh, Pt, or Pd.[55]

OS **VI**, 432.

12-2 Migration of Double Bonds

3/Hydro-de-hydrogenation

$$C_5H_{11}\text{—}CH_2\text{—}CH{=}CH_2 \xrightarrow[Me_2SO]{KNH_2} C_5H_{11}\text{—}CH{=}CH\text{—}CH_3$$

The double bonds of many unsaturated compounds are shifted[56] on treatment with strong bases.[57] In many cases, equilibrium mixtures are obtained and the thermodynamically most stable isomer predominates.[58] Thus, if the new double bond can be in conjugation with one already present or with an aromatic ring, the migration favors the conjugated compound.[59] If the choice is between an exocyclic and an endocyclic double bond (particularly with six-membered rings), it generally chooses the latter. In the absence of considerations like these, Zaitsev's rule (p. 1497) applies and the double bond goes to the carbon with the fewest hydrogens. All these considerations lead us to predict that terminal alkenes can be isomerized to internal ones, nonconjugated alkenes to conjugated, exo six-membered-ring alkenes to endo, and so on, and not the other way around. This is indeed usually the case.

[55]See, for example, Atkinson, J.G.; Luke, M.O.; Stuart, R.S. *Can. J. Chem.* ***1967***, *45*, 1511.

[56]For a list of methods used to shift double and triple bonds, with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, ***1999***, pp. 220–226, 567–568.

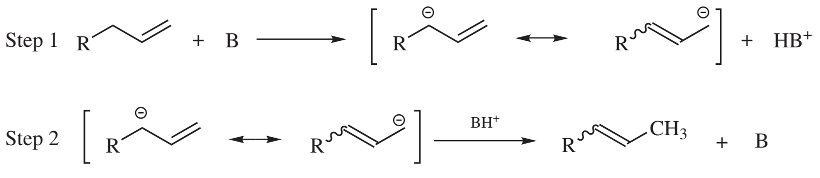
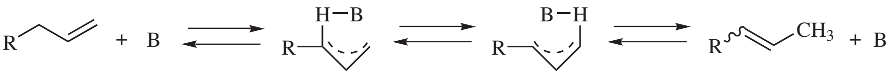
This reaction, for which the term *prototropic rearrangement* is sometimes used, is an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by a base to give a resonance-stabilized carbanion, which then combines with a proton at the position that will give the more stable alkene:[60]



This mechanism is exactly analogous to the allylic-rearrangement mechanism for nucleophilic substitution (p. 468). UV spectra of allylbenzene and 1-propenylbenzene in solutions containing NH_2^- are identical, which shows that the same carbanion is present in both cases, as required by this mechanism.[61] The acid BH^+ protonates the position that will give the more stable product, although the ratio of the two possible products can vary with the identity of BH^+.[62] It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.[63] The intramolecular nature has been ascribed to a *conducted tour mechanism* (p. 761) in which the base leads the proton from one carbanionic site to the other (**13** → **14**).[64]



13 **14**

Triple bonds can also migrate in the presence of bases,[65] but through the allene intermediate:[66]

$$R{-}CH_2{-}C{\equiv}CH \rightleftharpoons R{-}CH{=}C{=}CH_2 \rightleftharpoons R{-}C{\equiv}C{-}CH_3$$

[66]For a review of rearrangements involving allenes, see Huntsman, W.D., in Patai, S. *The Chemistry of Ketenes, Allenes, and Related Compounds*, pt. 2; Wiley, NY, ***1980***, pp. 521–667.

In general, strong bases, for example, $NaNH_2$, convert internal alkynes to terminal alkynes (a particularly good base for this purpose is potassium 3-aminopropylamide $NH_2CH_2CH_2CH_2NHK$[67]), because the equilibrium is shifted by formation of the acetylid ion. With weaker bases such as NaOH (which are not strong enough to remove the acetylenic proton), the internal alkynes are favored because of their greater thermodynamic stability. In some cases the reaction can be stopped at the allene stage.[68] The reaction then becomes a method for the preparation of allenes.[69] The reaction of propargylic alcohols with tosylhydrazine, PPh_3, and DEAD also generates allenes.[70]

Double-bond rearrangements can also take place on treatment with acids. Both proton and Lewis[71] acids can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained, giving a carbocation, and then another is lost:

$$\text{Step 1} \qquad CH_3{-}CH_2{-}CH{=}CH_2 \ + \ H^+ \longrightarrow CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3$$

$$\text{Step 2} \qquad CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3 \longrightarrow CH_3{-}CH{=}CH{-}CH_3 \ + \ H^+$$

As in the case of the base-catalyzed reaction, the thermodynamically most stable alkene is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of 1-decene, for example, gives a mixture that contains not only 1-decene and *cis*- and *trans*-2-decene, but also the cis and trans isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable alkenes predominate, but many of them have stabilities that are close together. Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., $HF{-}PF_5$) are used.[72] If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

Double-bond isomerization can also take place in other ways. Nucleophilic allylic rearrangements were discussed in Chapter 10 (p. 468). Electrocyclic and sigmatropic rearrangements are treated at **18-27–18-35**. Double-bond migrations have also been accomplished photochemically,[73] and by means of metallic ion (most

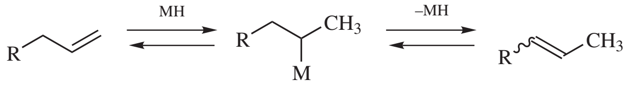
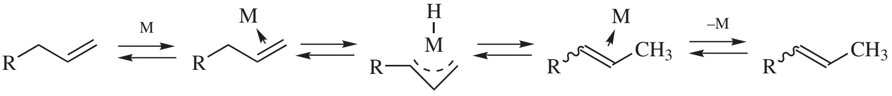
[73]Schönberg, A. *Preparative Organic Photochemistry*, Springer, NY, ***1968***, pp. 22–24.

often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.[74] In the latter case, there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition–elimination mechanism*:



The other mechanism, called the *π-allyl complex mechanism*, does not require external hydrogen and proceeds by hydrogen abstraction to form the η^3-π-allyl complex **15** (see p. 117 and **10-60**).



15

Another difference between the two mechanisms is that the former involves 1,2- and the latter 1,3-shifts. The isomerization of 1-butene by rhodium(I) is an example of a reaction that takes place by the metal hydride mechanism,[75] while an example of the π-allyl complex mechanism is found in the $Fe_3(CO)_{12}$-catalyzed isomerization of 3-ethyl-1-pentene.[76] A palladium catalyst was used to convert alkynones $RCOC{\equiv}CCH_2CH_2R'$ to 2,4-alkadien-1-ones, $RCOCH{=}CHCH{=}CHCHR'$.[77] The reaction of an en-yne with $HSiCl_3$ and a palladium catalyst generated an allene with moderate enantioselectivity (see p 148 for chiral allenes).[78]

The metal catalysis method has been used for the preparation of simple enols, by isomerization of allylic alcohols, for example,[79] these enols are stable enough for isolation (see p. 231), but slowly tautomerize to the aldehyde or ketone, with half-lives ranging from 40 to 50 min to several days.[79]

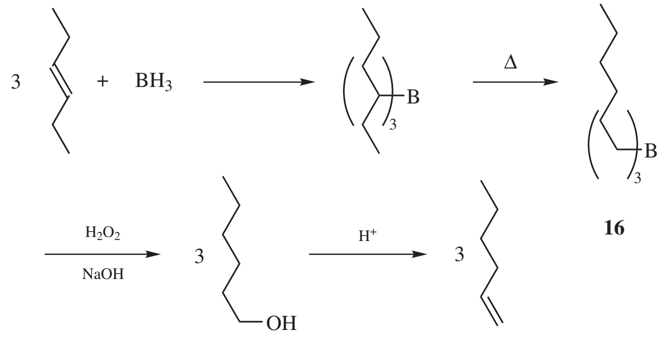
No matter which of the electrophilic methods of double-bond shifting is employed, the thermodynamically most stable alkene is usually formed in the largest amount in most cases, although a few anomalies are known. However, an indirect method of double-bond isomerization us known, leading to migration in the other direction. This involves conversion of the alkene to a borane (**15-16**), rearrangement of the borane (**18-11**), oxidation and hydrolysis of the newly formed borane to the alcohol **17** (see **12-31**), and dehydration of the alcohol (**17-1**) to the alkene. The reaction is driven by the fact that with heating the addition of borane is reversible, and the equilibrium favors formation of the less sterically hindered borane, which is **16** in this case.



16

17

Since the migration reaction is always toward the end of a chain, terminal alkenes can be produced from internal ones, so the migration is often opposite to that with the other methods. Alternatively, the rearranged borane can be converted directly to the alkene by heating with an alkene of molecular weight higher than that of the product (**17-15**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.[80]

If a hydroxy group is present in the chain, *it* may lose a proton, so that a ketone is the product, for example,[81]

$$R_2C{=}CHCH_2CH_2CHOHCH_3 \xrightarrow[\text{acid}]{\text{polyphosphoric}} R_2CHCH_2CH_2CH_2COCH_3$$

Similarly, α-hydroxy triple-bond compounds have given α,β-unsaturated ketones.[82]

[80]For example, see Kropp, P.J.; Krauss, H.J. *J. Am. Chem. Soc.* ***1967***, *89*, 5199; Reardon, Jr., E.J.; Krauss, H. *J. Am. Chem. Soc.* ***1971***, *93*, 5593; Duhaime, R.M.; Lombardo, D.A.; Skinner, I.A.; Weedon, A.C. *J. Org. Chem.* ***1985***, *50*, 873.

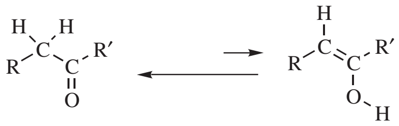
12-3 Keto–Enol Tautomerization

3/*O*-Hydro-de-hydrogenation



The tautomeric equilibrium between enols and ketones or aldehydes (keto–enol tautomerism) is a form of prototropy,[83] but is not normally a preparative reaction. For some ketones, however, both forms can be prepared (see p. 101 for a discussion of this and other aspects of tautomerism). Keto–enol tautomerism occurs in systems containing one or more carbonyl groups linked to sp^3 carbons bearing one or more hydrogen atoms. The keto tautomer is generally more stable than the enol tautomer for neutral systems, and for most ketones and aldehydes only the keto form is detectable under ordinary conditions. The availability of additional intramolecular stabilization through hydrogen bonding or complete electron delocalization (as in phenol), may cause the enol tautomer to be favored.

Keto–enol tautomerism cannot take place without at least a trace of acid or base,[84] since the acidic or basic center or both in the tautomeric substance is too weak.[85] In this equilibrium, the heteroatom is the basic site the proton is the acidic site. For tautomerism in general (see p 98),[86] the presence of an acid or a base is not necessary to initiate the isomerization since each tautomeric substance possesses amphiprotic properties.[85] Keto-enol tautomerism is therefore the exception.

Polar protic solvents, such as water or alcohol, may participate in the proton transfer by forming a cyclic or a linear complex with the tautomers.[87] Whether the complex formed is cyclic or linear depends on the conformation and configuration of the tautomers. In a strongly polar aprotic solvent and in the presence of an acid or a base, the tautomeric molecule may lose or gain a proton and form the corresponding mesomeric anion or cation, which, in turn, may gain or lose a proton, respectively, and yield a new tautomeric form.[88] The structural features of the carbonyl compound influences the equilibrium.[89] There is a rate acceleration when $LiN(SiMe_3)_2$–NEt_3 is used.[90] It has been shown that ring strain plays no significant role on the rate of base-catalyzed enolization.[91] Differing conjugative stabilization by CH-π orbital overlap does not directly influence stereoselectivity, and steric effects are generally not large enough to cause the several kcal/mol energy difference seen between transition structures unless there is exceptional crowding.[92] It is noted that sterically stabilized enols are known,[93] including arylacetaldehydes.[94] Torsional strain involving vicinal bonds does contribute significantly to stereoselectivity in enolate formation.[92]

The acid and base catalyzed mechanisms are identical to those in **12-2**.[95]
Acid-catalyzed

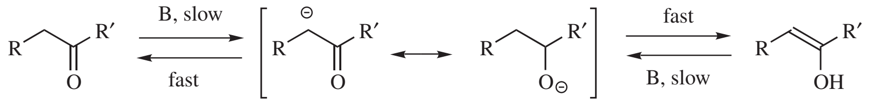
Base-catalyzed[96]



18

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of microscopic reversibility.[97] As expected from mechanisms in which the C–H bond is broken in the rate-determining step, substrates of the type RCD_2COR show deuterium isotope effects (of ~5) in both the basic-[98] and the acid[99]-catalyzed processes. The keto–enol/enolate anion equilibrium has been studied in terms of the influence of β-oxygen[100] or β-nitrogen[101] substituents.

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure, the reactions do have their preparative aspects. If a full equivalent of base per equivalent of ketone is used, the enolate ion (**18**) is formed and can be isolated[102] (see, e.g., the alkylation reaction in **10-68**).[103] When enol ethers or esters are hydrolyzed, the enols initially formed immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to an stereogenic carbon α to a carbonyl group (as in **19**) is treated with acid or base, racemization results.[104]

[96]Another mechanism for base-catalyzed enolization has been reported when the base is a tertiary amine: See Bruice, P.Y. *J. Am. Chem. Soc.* ***1983***, *105*, 4982; ***1989***, *111*, 962; ***1990***, *112*, 7361.

[97]It has been proposed that the acid-catalyzed ketonization of simple enols is concerted; that is, both of the processes shown in the equation take place simultaneously. This would mean that in these cases the forward reaction is also concerted. For evidence in favor of this proposal, see Capon, B.; Siddhanta, A.K.; Zucco, C. *J. Org. Chem.* ***1985***, *50*, 3580. For evidence against it, see Chiang, Y.; Hojatti, M.; Keeffe, J.R.; Kresge, A.J.; Schepp, N.P.; Wirz, J. ***1987***, *109*, 4000 and references cited therein.

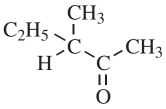
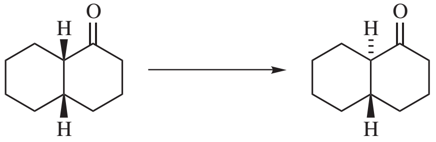
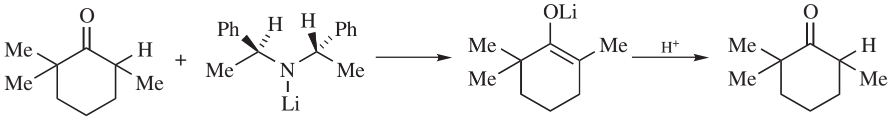
If there is another





19 *cis*-Decalone *trans*-Decalone

stereogenic center in the molecule, the less stable epimer can be converted to the more stable one in this manner, and this is often done. For example, *cis*-decalone can be equilibrated to the trans isomer. Isotopic exchange can also be accomplished at the a position of an aldehyde or ketone in a similar manner. The role of additives, such as $ZnCl_2$ on the stereogenic enolization reactions using chiral cases has been discussed.[105] Enantioselective enolate anion protonation reactions have been studied.[106] For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back, but in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic. In cyclic compounds, cis- to trans-isomerization can occur via the enol.[107]



20 Racemic **21** **22** **20** Optically active

In the case of the ketone **20**, a racemic mixture was converted to an optically active mixture (optical yield 46%) by treatment with the chiral base **21**.[108] This happened because **21** reacted with one enantiomer of **20** faster than with the other (an example of kinetic resolution). The enolate **22** must remain coordinated with the chiral amine, and it is the amine that reprotonate **22**, not an added proton donor.

Enolizable hydrogens can be replaced by deuterium (and ^{16}O by ^{18}O) by passage of a sample through a deuterated (or ^{18}O-containing) gas-chromatography column.[109]

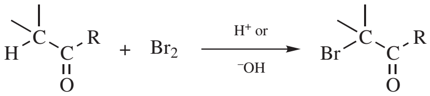
There are many enol-keto interconversions and acidification reactions of enolate ions to the keto forms listed in *Organic Syntheses*. No attempt is made to list them here.

B. Halogen Electrophiles

Halogenation of unactivated hydrocarbons is discussed in **14-1**.

12-4 Halogenation of Aldehydes and Ketones

Halogenation or **Halo-de-hydrogenation**



Aldehydes and ketones can be halogenated in the a position with bromine, chlorine, or iodine.[110] The reaction is not successful with fluorine.[111] Sulfuryl chloride,[112] $NaClO_2/Mn(acac)_3$,[113] $Me_3SiCl–Me_2SO$,[114] $Me_3SiCl–MnO_2$,[115] and cupric chloride[116] have been used as reagents for chlorination, and *N*-bromosuccinimide (see **14-3**),[117] *t*-BuBr–DMSO,[118] Me_3SiBr–DMSO,[119] tetrabutylammonium tribromide,[120] and bromine • dioxane on silica with microwave irradiation[121] for bromination. Bromination of methyl ketones was done using PhI(OH)OTs with microwave irradiation, followed by treatment with $MgBr_2$ and microwave irradiation.[122] α-Chloro aldehydes are formed with Cl_2 and a catalytic amount of tetraethylammonium chloride.[123] Chlorination of aldehydes with good enantioselectivity was

[123]Bellesia, F.; DeBuyck, L.; Ghelfi, F.; Pagnoni, U.M.; Parson, A.F.; Pinetti, A. *Synthesis* ***2003***, 2173.

reported using a chlorinated quinone and L-proline, with the reaction proceeding via the chiral enamine.[124] Iodination has been accomplished with I_2–$HgCl_2$,[125] with I_2-cerium(IV) ammonium nitrate,[126] and with iodine using 1-chloromethyl-4-fluoro-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate), known as Selectfluor F–TEDA–BF_4, in methanol.[127] Treatment of a ketone with (hydroxy-*p*-nitrobenzene-sulfonyloxy)benzene followed by SmI_2 give the α-iodo ketone.[128] Methyl ketones react with *N*-iodosuccinimide (NIS) and tosic acid with microwave irradiation without solvent to give the α-iodo ketone.[129] Several methods have been reported for the preparation of α-fluoro aldehydes and ketones.[130] Another Selectfluor, 1-Fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane bis(tetrafluoroborate) has been used for the monofluorination of ketones,[131] as has a mixture of KI–KIO_3–H_2SO_4.[132] Active compounds, such as β-keto esters and β-diketones, have been fluorinated with an *N*-fluoro-*N*-alkylsulfonamide[133] (this can result in enantioselective fluorination, if an optically active *N*-fluorosulfonamide is used[134]), with F_2/N_2–HCOOH,[135] with NF_3O/Bu_4NOH,[136] and with acetyl hypofluorite.[137] The last reagent also fluorinates simple ketones in the form of their lithium enolates.[138]

For unsymmetrical ketones, the preferred position of halogenation is usually the more substituted: a CH group, then a CH_2 group, and then CH_3;[139] however, mixtures are frequent. With aldehydes the aldehydic hydrogen is sometimes replaced (see **14-4**). It is also possible to prepare di- and polyhalides. When basic catalysts are used, one a position of a ketone is completely halogenated before the other is

attacked, and the reaction cannot be stopped until all the hydrogens of the first carbon have been replaced (see below). If one of the groups is methyl, the haloform reaction (**12-44**) takes place. With acid catalysts, it is easy to stop the reaction after only one halogen has entered, although a second halogen can be introduced by the use of excess reagent. In chlorination the second halogen generally appears on the same side as the first,[140] while in bromination the α,α'-dibromo product is found.[141] Actually, with both halogens it is the α,α-dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the α,α' isomer.[140] α,α'-Dichloro ketones are formed by reaction of a methyl ketone with an excess of $CuCl_2$ and LiCl in DMF[142] or with HCl and H_2O_2 in methanol.[143] Aryl methyl ketones can be dibrominated ($ArCOCH_3 \rightarrow ArCOCHBr_2$) in high yields with benzyltrimethylammonium tribromide.[144] Active methylene compounds are chlorinated with NCS and $Mg(ClO_4)_2$.[145] Similar chlorination in the presence of a chiral copper catalyst led to α-chlorination with modest enantioselectivity.[146]

It is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate. The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is

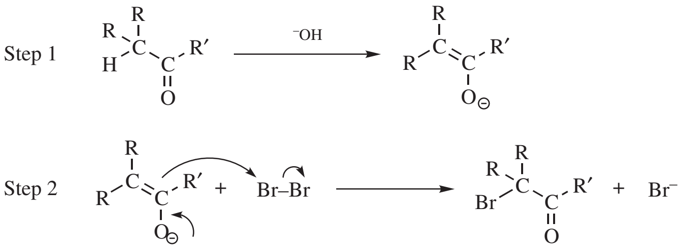
[146]Marigo, M.; Kumaragurubaran, N.; Jørgensen, K.A. *Chem. Eur. J.* ***2004***, *10*, 2133.

The first step, as we have already seen (**12-3**), actually consists of two steps. The second step is very similar to the first step in electrophilic addition to double bonds (p. 999). There is a great deal of evidence for this mechanism: (*1*) the rate is first order in substrate; (*2*) bromine does not appear in the rate expression at all,[147] a fact consistent with a rate-determining first step;[148] (*3*) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;[149] (*4*) the reaction shows an isotope effect; and (*5*) the rate of the step 2–step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.[150]

With basic catalysts the mechanism may be the same as that given above (since bases also catalyze formation of the enol), or the reaction may go directly through the enolate ion without formation of the enol:



It is difficult to distinguish the two possibilities. It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three a halogens on the same side of the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogens, that is, a CHX group is more acidic than a CH_2 group, so that initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate. Other halogenating agents can be used in this reaction. Reaction of a lithium enolate anion with tosyl chloride gave the corresponding α-chloro ketone.[151] When an aldehyde was treated with a catalytic amount of 2,5-lutidine to generate the enolate anion, reaction with 35% HCl in dichloromethane gave the α,α-dichloroaldehyde.[152]

[147]When the halogenating species is at low concentration or has a low reactivity, it can appear in the rate expression. The reaction becomes first order in the halogenating species. See, for example, Tapuhi, E.; Jencks, W.P. *J. Am. Chem. Soc.* ***1982***, *104*, 5758. For a case in which the reaction is first order in bromine, even at relatively high Br_2 contentration, see Pinkus, A.G.; Gopalan, R. *J. Am. Chem. Soc.* ***1984***, *106*, 2630. For a study of the kinetics of iodination, see Pinkus, A.G.; Gopalan, R. *Tetrahedron* ***1986***, *42*, 3411.

[148]Under some conditions it is possible for step 2 to be rate-determining: Deno, N.C.; Fishbein, R. *J. Am. Chem. Soc.* ***1973***, *95*, 7445.

Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with *N*-bromo- or *N*-chlorosuccinimide.[153] The desired halo

ketone is formed in high yield. Another method for achieving the same result involves bromination of the appropriate lithium enolate at a low temperature[154] (see p. 630 for the regioselective formation of enolate ions). In a similar process, α-halo aldehydes have been prepared in good yield by treatment of silyl enol ethers $R_2C{=}CHOSiMe_3$ with Br_2 or Cl_2,[155] with sulfuryl chloride SO_2Cl_2;[156] or with I_2 and silver acetate.[157] Other chlorinating agents can be used with a variety of silyl enol ethers to generate α-chloroketones with good enantioselectivity, including $ZrCl_4$ in conjunction with an α,α-dichloromalonate ester.[158] Silyl enol ethers can also be fluorinated, with XeF_2[159] or with 5% F_2 in N_2 at –78°C in $FCCl_3$.[160] Enol acetates have been regioselectively iodinated with I_2 and either thallium(I) acetate[161] or copper(II) acetate.[162]

α,β-Unsaturated ketones can be converted to α-halo-α,β-unsaturated ketones by treatment with phenylselenium bromide or chloride,[163] and to α-halo-β,γ-unsaturated ketones by two-phase treatment with HOCl.[164] Conjugated ketones were converted to the α-bromo conjugated ketone (a vinyl bromide) using the Dess–Martin periodinane (see p. 1723) and tetraethylammonium bromide.[165]

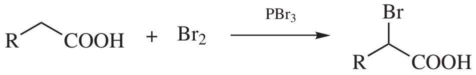
12-5 Halogenation of Carboxylic Acids and Acyl Halides

Halogenation or **Halo-de-hydrogenation**



Using a phosphorus halide as catalyst, the α hydrogens of carboxylic acids can be replaced by bromine or chlorine.[166] The reaction, known as the *Hell–Volhard–Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two α hydrogens, one or both may be replaced, although it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed from the carboxylic acid and the catalyst. The acids alone are inactive, except for those with relatively high enol content, such as malonic acid. Less than one full mole of catalyst (per mole of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see **16-79**). Each molecule of acid is α halogenated while it is in the acyl halide stage. The halogen from the catalyst does not enter the α position. For example, the use of Cl_2 and PBr_3 results in α chlorination, not bromination. As expected from the foregoing, acyl halides undergo a halogenation without a catalyst. An enantioselective α-halogenation was reported yielding via an alkaloid catalyzed reaction of acyl halides with perhaloquinone-derived reagents to give to chiral α-haloesters.[167] So do anhydrides and many compounds that enolize easily (e.g., malonic ester and aliphatic nitro compounds). The mechanism is usually regarded as proceeding through the enol as in **12-4**.[168] If chlorosulfuric acid $ClSO_2OH$ is used as a catalyst, carboxylic acids can be α-iodinated,[169] as well as chlorinated or brominated.[170] *N*-Bromosuccinimide in a mixture of sulfuric acid–trifluoroacetic acid can mono-brominate simple carboxylic acids.[171]

A number of other methods exist for the a halogenation of carboxylic acids or their derivatives.[172] Under electrolytic conditions with NaCl, malonates are converted to 2-chloro malonates.[173] Acyl halides can be a brominated or chlorinated by use of *N*-bromo- or *N*-chlorosuccinimide and HBr or HCl.[174] The latter is an ionic, not a free-radical halogenation (see **14-3**). Direct iodination of carboxylic acids has been achieved with I_2–Cu(II) acetate in HOAc.[175] Acyl chlorides can

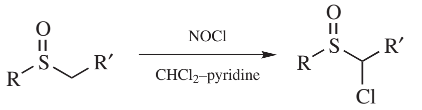
12-6 Halogenation of Sulfoxides and Sulfones

Halogenation or **Halo-de-hydrogenation**



Sulfoxides can be chlorinated in the α position[180] by treatment with Cl_2[181] or *N*-chlorosuccinimide,[182] in the presence of pyridine. These methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO_2Cl_2 in CH_2Cl_2,[183] or with $TsNCl_2$.[184] The bromination of sulfoxides with bromine[185] and with NBS-bromine[186] have also been reported. Sulfones have been chlorinated by treatment of their conjugate bases $RSO_2C^{\ominus}$ HR′ with various reagents, among them SO_2Cl_2, CCl_4,[187] *N*-chlorosuccinimide,[188] and hexachloroethane.[189] The α fluorination of sulfoxides has been accomplished in a two-step procedure. Treatment with diethylaminosulfur trifluoride Et_2NSF_3 (DAST) produces an

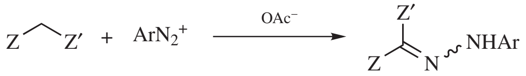
α-fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperoxybenzoic acid gives the sulfoxide.[190]

C. Nitrogen Electrophiles

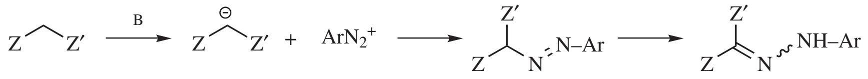
12-7 Aliphatic Diazonium Coupling

Arylhydrazono-de-dihydro-bisubstitution



If a C–H bond is acidic enough, it couples with diazonium salts in the presence of a base, most often aqueous sodium acetate.[191] The reaction is commonly carried out on compounds of the form Z–CH_2–Z′, where Z and Z′ are as defined on p. 1358, for example, β-keto esters, β-keto amides, malonic ester.

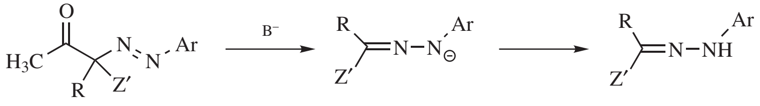
The mechanism is probably of the simple S_E1 type:



23

Aliphatic azo compounds in which the carbon containing the azo group is attached to a hydrogen are unstable and tautomerize to the isomeric hydrazones (**23**), which are therefore the products of the reaction.

When the reaction is carried out on a compound of the form Z–CHR–Z′, so that the azo compound does not have a hydrogen that can undergo tautomerism, if at least one Z is acyl or carboxyl, this group usually cleaves:



24

so the product in this case is also the hydrazone, and not the azo compound. In fact, compounds of the type **24** are seldom isolable from the reaction, although this has been accomplished.[192] The cleavage step shown is an example of **12-43** and, when a carboxyl group cleaves, of **12-40**. The overall process in this case is called the *Japp–Klingemann reaction*[193] and involves conversion of a ketone (**25**) or a

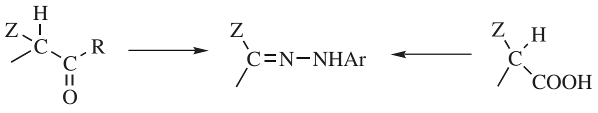
carboxylic acid (**26**)



25 **26** **27**

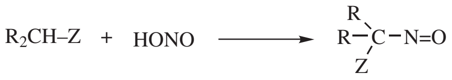
to a hydrazone (**27**). When an acyl and a carboxyl group are both present, the leaving group order has been reported to be MeCO > COOH > PhCO.[194] When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

OS **III**, 660; **IV**, 633.

12-8 Nitrosation at a Carbon Bearing an Active Hydrogen

Hydroxyimino-de-dihydro-bisubstitution

Nitrosation or **Nitroso-de-hydrogenation**



Carbons adjacent to a Z group (as defined on p. 622) can be nitrosated with nitrous acid or alkyl nitrites.[195] The initial product is the *C*-nitroso compound, but these are stable only when there is no hydrogen that can undergo tautomerism. When there is, the product is the more stable oxime. The situation is analogous to that with azo compounds and hydrazones (**12-7**). The mechanism is similar to that in **12-7**:[196] $R{-}H \rightarrow R^- + {}^+N{=}O \rightarrow R{-}N{=}O$. The attacking species is either NO^+ or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation **12-4**):

Evidence is that the reaction, in the presence of X^- (Br^-, Cl^-, or SCN^-), was first order in ketone and in H^+, but zero order in HNO_2 and X^-.[197] Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species NOX is formed by $HONO + X^- + H^+ \rightarrow HOX + H_2O$. In

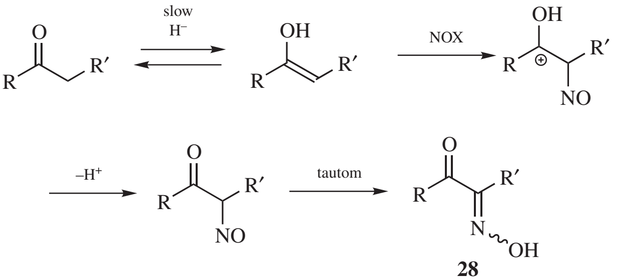
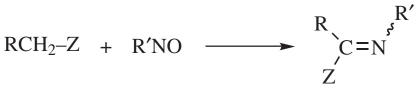
the cases of $F_3CCOCH_2COCF_3$ and malononitrile the nitrosation went entirely through the enolate ion rather than the enol.[198]



28

As in the Japp–Klingemann reaction, when Z is an acyl or carboxyl group (in the case of R_2CH–Z), it can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of **12-4**, the silyl enol ether of a ketone can be used instead of the ketone itself.[199] Good yields of α-oximinoketones (**28**) can be obtained by treating ketones with *tert*-butyl thionitrate.[200]

Imines can be prepared in a similar manner by treatment of an active hydrogen compound with a nitroso compound:



Alkanes can be nitrosated photochemically, by treatment with NOCl and UV light.[201] For nitration at an activated carbon, see **12-9**. Trialkyltin enol ethers ($C{=}C{-}O{-}SnR_3$) react with PhNO to give α-(N-hydroxylamino)ketones.[202]

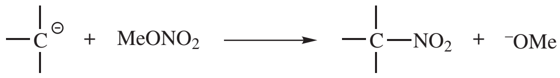
[201]For a review, see Pape, M. *Fortschr. Chem. Forsch.* ***1967***, *7*, 559.

[202]Momiyama, N.; Yamamoto, H. *Org. Lett.* ***2002***, *4*, 3579.

Nitration of alkanes[203] can be carried out in the gas phase at ~400°C or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.[204] A free-radical mechanism is involved.[205]



Activated positions (e.g., ZCH_2Z' compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,[206] or by alkyl nitrates under alkaline conditions.[207] In the latter case, it is the carbanionic form of the substrate that is actually nitrated. What is isolated under these alkaline conditions is the conjugate base of the nitro compound. Yields are not high. Of course, the mechanism in this case is not of the free-radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of **12-7** and **12-8**). Positions activated by only one electron-withdrawing group, for example, a positions of simple ketones, nitriles, sulfones, or *N*,*N*-dialkyl amides, can be nitrated with alkyl nitrates if a very strong base, for example, *t*-BuOK or $NaNH_2$, is present to convert the substrate to the carbanionic form.[208]

Electrophilic nitration of alkanes has been performed with nitronium salts, for example, $NO_2^+\ PF_6^-$ and with HNO_3–H_2SO_4 mixtures, but mixtures of nitration and cleavage products are obtained and yields are generally low.[209] The reaction of alkanes with nitric acid and *N*-hydroxysuccinimide (NHS), however, gave moderate-to-good yields of the corresponding nitroalkane.[210] Similar nitration was accomplished with NO_2, NHS and air.[211]

Aliphatic nitro compounds can be a nitrated [$R_2C^{\ominus}NO_2 \rightarrow R_2C(NO_2)_2$] by treatment of their conjugate bases $RCNO_2$ with $NO_2^-$and $K_3Fe(CN)_6$.[212]

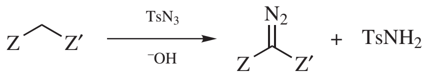
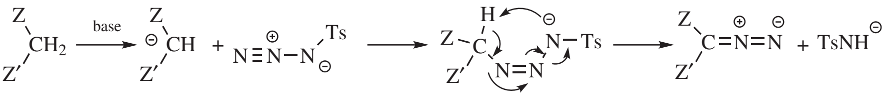
12-10 Direct Formation of Diazo Compounds

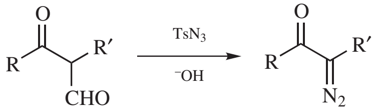
Diazo-de-dihydro-bisubstitution



Compounds containing a CH_2 bonded to two Z groups (active methylene compounds, with Z as defined on p. 622) can be converted to diazo compounds on treatment with tosyl azide in the presence of a base.[214] The use of phase-transfer catalysis increases the convenience of the method.[215] *p*-Dodecylbenzenesulfonyl azide,[216] methanesulfonyl azide,[217] and *p*-acetamidobenzenesulfonyl azide[218] also give the reaction. The reaction, which is called the *diazo-transfer reaction*, can also be applied to other reactive positions (e.g., the 5 position of cyclopentadiene).[219] The mechanism is probably as follows:



A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an α-formyl ketone (**16-85**) and then treating it with tosyl azide. As in the similar cases of



12-7 and **12-8**, the formyl group is cleaved during the reaction.[220]

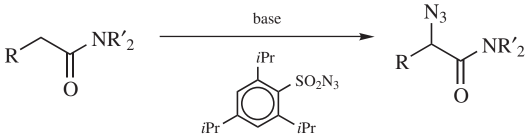
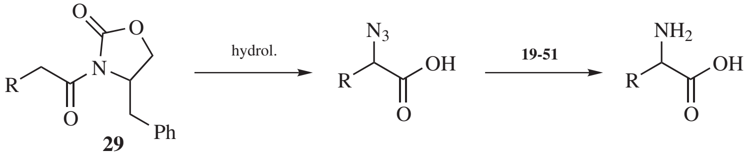
12-11 Conversion of Amides to α-Azido Amides

Azidation or **Azido-de-hydrogenation**



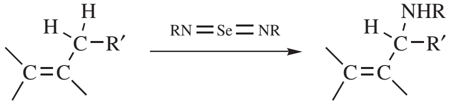
In reaction **12-10**, treatment of Z–CH_2–Z′ with tosyl azide gave the α-diazo compound via diazo transfer. When this reaction is performed on a compound with a single Z group such as an amide, formation of the azide becomes a competing process via the enolate anion.[221] Factors favoring azide formation rather than diazo transfer include K^+ as the enolate counterion rather than Na^+ or Li^+ and the use of 2,4,6-triisopropylbenzenesulfonyl azide rather than TsN_3. When the reaction was applied to amides with a chiral R', such as the oxazolidinone derivative **29**, it was highly stereoselective, and the product could be converted to an optically active amino acid.[221]



29

12-12 Direct Amination at an Activated Position

Alkyamino-de-hydrogenation, and so on



R = *t*-Bu, Ts

Alkenes can be aminated[222] in the allylic position by treatment with solutions of imido selenium compounds R–N=Se=N–R.[223] The reaction, which is similar to the allylic oxidation of alkenes with SeO_2 (see **19-14**), has been performed with R = *t*-Bu and R = Ts. The imido sulfur compound TsN=S=NTs has also been used,[224] as well

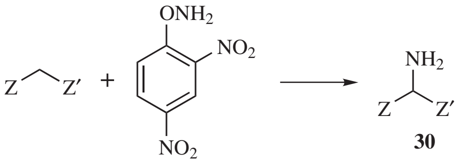
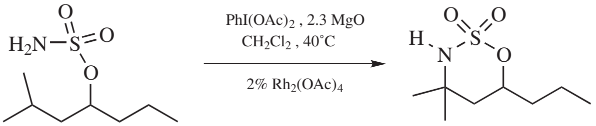
as $PhNHOH–FeCl_2/FeCl_3$.[225] Benzylic positions can be aminated with *t*-BuOO-CONHTs in the presence of a catalytic amount of $Cu(OTf)_2$.[226] In another reaction, compounds containing an active hydrogen can be converted to primary amines (**30**) in moderate yields by treatment with *O*-(2,4-dinitrophenyl)hydroxylamine.[227]



30



31 **32**

Tertiary alkyl hydrogen can be replaced in some cases via C–H nitrogen insertion. The reaction of sulfamate ester **31** with $PhI(OAc)_2$, MgO and a dinuclear Rh carboxylate catalyst, for example, generated oxathiazinane **32**.[228] This transformation is a formal oxidation, and primary carbamates have been similarly converted to oxazolidin-2-ones.[229]

In an indirect amination process, acyl halides are converted to amino acids.[230] Reaction of the acyl halide with a chiral oxazolidinone leads to a chiral amide, which reacts with the N=N unit of a dialkyl azodicarboxylate[$R^2O_2C–N=N–CO_2R'$]. Hydrolysis and catalytic hydrogenation leads to an amino acid with good enantioselectivity.[226]

Carbonylnitrenes: NCOW (W = R′, Ar, or OR′) are very reactive species (p. 293) and insert into the C–H bonds of alkanes to give amides (W = R′ or Ar) or carbamates (W = OR′).[231] The nitrenes are generated as discussed on p. 293. The order of reactivity among alkane C–H bonds is tertiary > secondary > primary.[232] Indications are that in general it is only singlet and not triplet nitrenes that insert.[233] Retention of configuration is found at a chiral carbon.[234] The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (**12-21**). Other nitrenes [e.g., cyanonitrene (NCN)[235] and arylnitrenes (NAr)[236]] can also insert into C–H bonds, but alkylnitrenes usually undergo rearrangement before they can react with the alkane. *N*-Carbamoyl nitrenes undergo insertion reactions that often lead to mixtures of products, but exceptions are known,[237] chiefly in cyclizations.[238] For example, heating of 2-(2-methylbutyl)phenyl azide gave ~60% 2-ethyl-2-methylindoline.[234] Enantioselective nitrene insertion reactions are known.[239]

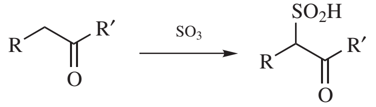
Sulfonation or **Sulfo-de-hydrogenation**



Ketones, carboxylic esters (including lactones),[240] and amides (including lactams)[241] can be sulfenylated[242] in the α position by conversion to the enolate ion with a base, such as lithium *N*-isopropylcyclohexylamide and subsequent treatment with a disulfide.[243] The reaction, shown above for ketones, involves nucleophilic substitution at sulfur. Analogously, α-phenylseleno ketones RCH(SePh)COR′ and α-phenylseleno esters RCH(SePh)COOR′ can be prepared[244] by treatment of the corresponding enolate anions with PhSeBr,[245] PhSeSePh,[246] or benzeneseleninic anhydride PhSe(O)OSe(O)Ph.[247] Another method for the introduction of a phenylseleno group into the α position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with PhSeCl (but not PhSeBr) at room temperature.[248] This procedure is also successful for aldehydes, but not for carboxylic esters. *N*-Phenylselenophthalimide has been used to convert ketones[249] and aldehydes[250] to the α- PhSe derivative. In another method that avoids the use of PhSeX reagents, a ketone enolate is treated with selenium to give an R′COCHRSe– ion, which is treated with MeI, producing the α-methylseleno ketone R′COCHRSeMe.[251] This method has also been applied to carboxylic esters.

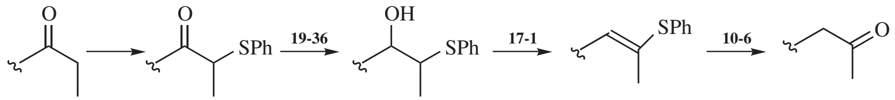
Silyl enol ethers are converted to α-thioalkyl and α-thioaryl ketones via a sulfenylation method, driven by aromatization of an added quinone mono-*O*,*S*-acetal in the presence of Me_3SiOTf.[252]

The α-seleno and α-sulfenyl carbonyl compounds prepared by this reaction can be converted to α,β-unsaturated carbonyl compounds (**17-12**). The sulfenylation reaction has also been used[253] as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.[254]



OS VI, 23, 109; 68, 8.

Aldehydes, ketones, and carboxylic acids containing α hydrogens can be sulfonated with sulfur trioxide.[255] The mechanism is presumably similar to that of **12-4**. Sulfonation has also been accomplished at vinylic hydrogen.

OS **VI**, 23, 109; **VIII**, 550. OS **IV**, 846, 862.

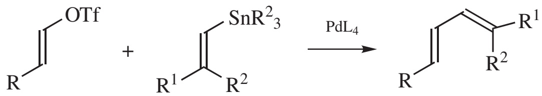
12-15 Arylation and Alkylation of Alkenes

Alkylation or **Alkyl-de-oxysulfonation (de-halogenation)**, **Arylation** or **Aryl-de-oxysulfonation (de-halogenation)**, and so on



Vinyl triflates ($C{=}C\text{-}OSO_2CF_3$) react with vinyl tin derivatives in the presence of palladium catalysts to form dienes, in what is known as the *Stille coupling*.[256] Vinyl triflates can be prepared from the enolate by reaction with *N*-phenyl triflimide.[257] Vinyltin compounds are generally prepared by the reaction of an alkyne with an trialkyltin halide (see **15-17** and **15-21**).[258] Still cross-coupling reactions are quite important.[259] Stille reactions are compatible with many functional groups,

proceed with a retention of geometry of the C=C units, and are usually regiospecific with respect to the newly formed C–C σ-bond. Vinyl halides can be used,[260] and allenic tin compounds have been used.[261] Intamolecualr reactions are possible.[262] Stille coupling has been done using microwave irradiation,[263] in fluorous solvents,[264] and in supercritical carbon dioxide (see p. 415).[265] One-pot hydrostannylation/Stille coupling has been reported using catalytic amounts of tin with alkyne substrates reacting with vinyl halides.[266]

This reaction is highly stereoselective. Cine substitution is known with this reaction, and its mechanism has been studied.[267] Using $ArSnCl_3$ derivatives, Stille coupling can be done in aq. KOH.[268] A related reaction couples reagents with C=C–I^+Ph reagents, in the presence of a palladium catalyst.[269] Aryl halides[270] and heteroaryl halides[271] can be coupled to vinyltin reagents[272] using a palladium catalyst. Vinylation of heteroaryl triflates[273] also possible. Vinyl halides can be coupled to alkenes to form dienes.[274] The reaction of dihydrofurans with vinyl triflates and a palladium catalyst leads to a nonconjugated diene, **33**.[275] This example illustrates that the product is formed by an elimination step, as with the Heck reaction (**13-10**), and double bond migration can occur resulting in allylic rearrangement.

The accepted mechanism for the Stille reaction involves a catalytic cycle[276] in which an oxidative addition[277] and a reductive elimination step[278] are fast, relative to Sn/Pd transmetallation (the rate-determining step).[279] It appears that the more coordinatively unsaturated species, probably with a coordinated solvent molecule, is involved in the electrophilic substitution at tin. Another mechanism has been proposed, in which oxidative addition of the vinyl triflate to the ligated palladium gives a *cis*-palladium complex that isomerizes rapidly to *trans*-palladium complex, which then reacts with the organotin compound following a S_E2 (cyclic) mechanism, with release of a ligand.[280] This pathway gives a bridged intermediate, and subsequent elimination of $XSnBu_3$ yields a three-coordinate species cis-palladium complex, which readily gives the coupling product.[280]

Cyclopropylboronic acids (**12-28**) couple with vinylic halides[281] or vinyl triflates[282] to give vinylcyclopropanes, using a palladium catalyst. Vinyl borates (**12-28**) were coupled to vinyl triflates using a palladium catalyst.[283] In a variation, phenylboronic acid reacted with a symmetrical internal alkyne and a nickel catalyst to give a conjugated diene bearing a phenyl group.[284] Stille coupling to enols has been reported.[285] A variation of this latter reaction coupled vinyl triflates to vinyl ethers, without a palladium catalyst, but using microwave irradiation.[286] The

coupling of vinyl silanes to give the symmetrically conjugated diene using CuCl and air was reported.[287] Vinyl zinc halides were coupled to 1-halo enol ether to give a conjugated diene bearing a vinyl ether unit, using a palladium catalyst.[288] Tertiary propargyl alcohols (R-C=C-CMe_2OH) are coupled to conjugated alkenes in a Heck-like process using a palladium catalyst and oxygen to give the conjugated ene-yne.[289]

Coupling is not restricted to two vinyl units or an aryl with a vinyl. 1-Lithioalkynes were coupled to vinyl tellurium compounds (C=C–TeBu) using a nickel catalyst[290] or a palladium catalyst[291] to give a conjugated en-yne. 2-Alkynes (R-C=C-Me) react with $HgCl_2$, *n*-butyllithium, and $ZnBr_2$, sequentially, and then with vinyl iodides and a palladium catalyst to give the nonconjugated en-yne.[292] Alkynyl groups can be coupled to vinyl groups to give ene-ynes, via reaction of silver alkynes (Ag-C=C-R) with vinyl triflates and a palladium catalyst.[293] In the presence of CuI and a palladium catalyst, vinyl triflates[294] or vinyl halides[295] couple to terminal alkynes. Alkynyl zinc reagents (R-C=C-ZnBr) can be coupled to vinyl halides with a palladium catalyst to give the conjugate ene-yne.[296]

Alkyl groups can be coupled to a vinyl unit to give substituted alkenes. The reaction of vinyl iodides and EtZnBr, with a palladium catalyst, gave the ethylated alkene (C=C–Et).[297] A similar coupling reaction was observed with RZnI reagents and vinyl nitro compounds (C=C–NO_2), which gave the alkyne (C=C–R) with microwave irradiation.[298] Aliphatic alkyl bromides reacted with vinyltin compounds to give the alkylated alkene using a palladium catalyst.[299] Allylic tosylates were coupled to conjugated alkenes to give a non-conjugated diene using a palladium catalyst.[300] An internal coupling reaction was reported in which an alkenyl enamide (**34**) reacted with Ag_3PO_4 and a chiral palladium catalyst to give **35** enantioselectively.[301]

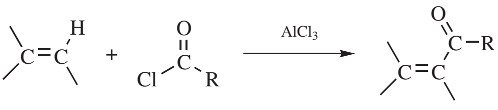
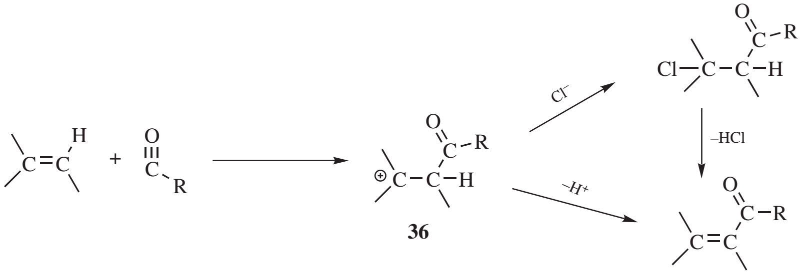
34 **35**

12-16 Acylation at an Aliphatic Carbon

Acylation or **Acyl-de-hydrogenation**



Alkenes can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a Friedel–Crafts reaction at an aliphatic carbon.[302] The product can arise by two paths. The initial attack is by the π-bond of the alkene unit on the acyl cation (RCO^+; or on the acyl halide free or complexed; see **11-17**) to give a carbocation, **36**.



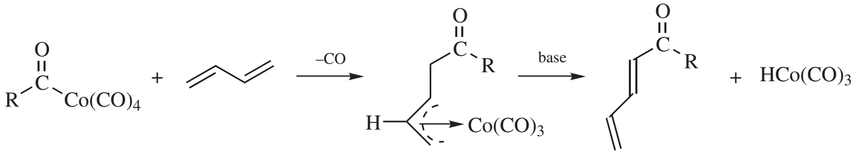
36

Ion **36** can either lose a proton or combine with chloride ion. If it loses a proton, the product is an unsaturated ketone; the mechanism is similar to the tetrahedral mechanism of Chapter 10, but with the charges reversed. If it combines with chloride, the product is a β-halo ketone, which can be isolated, so that the result is addition to the double bond (see **15-47**). On the other hand, the β-halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition–elimination mechanism. In the case of unsymmetrical alkenes, the more stable alkene is formed (the more highly substituted and/or conjugated alkene, following Markovnikov's rule, see p. 1019). Anhydrides and carboxylic acids (the latter with a proton acid such as anhydrous HF, H_2SO_4, or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some sub-

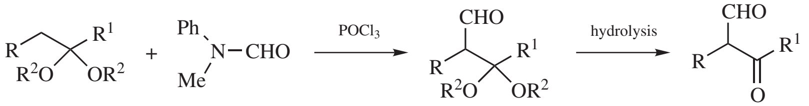
[302]For reviews, see Groves, E.E. *Chem. Soc. Rev.* ***1972***, *1*, 73; Satchell, D.P.N.; Satchell, R.S., in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, ***1966***, pp. 259–266, 270–273; Nenitzescu, C.D.; Balaban, A.T., in Olah A, G.A. *Friedel-Crafts and Related Reactions*, Vol. 3, Wiley, NY, ***1964***, pp. 1033–1152.

strates and catalysts double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.[303]

Conjugated dienes can be acylated by treatment with acyl- or alkylcobalt tetracarbonyls, followed by base-catalyzed cleavage of the resulting π-allyl carbonyl derivatives[304] (π-allyl metal complexes were discussed on p. 117. The reaction is very general. With unsymmetrical dienes, the acyl group generally substitutes most readily at a cis double bond, next at a terminal alkenyl group, and least readily at a trans double bond. The most useful bases are strongly basic, hindered amines, such as dicyclohexylethylamine. The use of an alkylcobalt tetracarbonyl $RCo(CO)_4$ gives the same product as that shown above. Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a palladium catalyst: $ROCH{=}CH_2 \rightarrow ROCH{=}CHCOAr$.[305]



Formylation of alkenes can be accomplished with *N*-disubstituted formamides and $POCl_3$.[306] This is an aliphatic Vilsmeier reaction (see **11-18**). Vilsmeier formylation can also be performed on the α position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes:[307] A variation of this reaction heated a 1,1-dibromoalkene with a secondary amine in aq. DMF to give the corresponding amide.[308]



Acetylation of acetals or ketals can be accomplished with acetic anhydride and BF_3-etherate.[309] The mechanism with acetals or ketals also involves attack at an

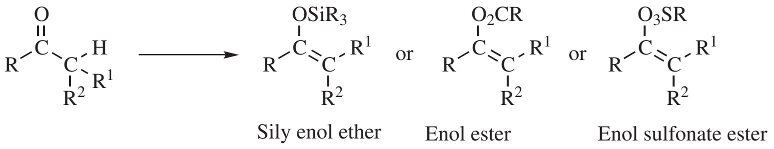
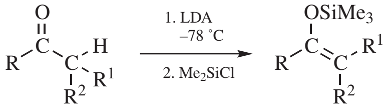
12-17 Conversion Of Enolates to Silyl Enol Ethers, Silyl Enol Esters, and Silyl Enol Sulfonate Esters

3/*O*-Trimethylsilyl-de-hydrogenation



Silyl enol ethers,[311] important reagents with a number of synthetic uses (see, e.g., **10-68**, **12-4**, **15-24**, **15-64**, **16-36**), can be prepared by base treatment of a ketone (converting it to its enolate anion) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.[312] Both strong bases, e.g., lithium diisopropylamide (LDA), and weaker bases (e.g. Et_3N) have been used for this purpose.



In some cases, the base and the silylating agent can be present at the same time.[313] Enolates prepared in other ways (e.g., as shown on p. 603) also give the reaction.[314] The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.[315] A particularly mild method for conversion of ketones

[310]See, for example, van der Zeeuw, A.J.; Gersmann, H.R. *Recl. Trav. Chim. Pays-Bas* ***1965***, *84*, 1535.

[315]Ladjama, D.; Riehl, J.J. *Synthesis* ***1979***, 504. This base has also been used for ketones: See Orban, J.; Turner, J.V.; Twitchin, B. *Tetrahedron Lett.* ***1984***, *25*, 5099.

or aldehydes to silyl enol ethers uses Me_3SiI and the base hexamethyldisilazane, $(Me_3Si)_2NH$.[316] Cyclic ketones can be converted to silyl enol ethers in the presence of acyclic ketones, by treatment with Me_3SiBr, tetraphenylstibonium bromide, Ph_4SbBr, and an aziridine.[317] bis(Trimethylsilyl)acetamide is an effective reagent for the conversion of ketones to the silyl enol ether, typically giving the thermodynamic product (see below).[318] Silyl enol ethers have also been prepared by the direct reaction of a ketone and a silane (R_3SiH) with a platinum complex catalyst.[319]

Unsymmetrical ketones can give the more substituted (thermodynamic) silyl enol ether or the less substituted (kinetic) product, depending on the use of thermodynamic conditions (protic solvents, e.g., ethanol, water, or ammonia; a base generating a conjugate acid stronger than the starting ketone; more ionic counterions, e.g., K or Na; higher temperatures and longer reaction times) or kinetic conditions (aprotic solvents, such as ether or THF; a base generating a conjugate acid weaker than the starting ketone; more covalent counterions, e.g., Li; lower temperatures and relatively short reaction times). Other reaction conditions have been developed to control or influence the relative amounts of kinetic or thermodynamic silyl enol ether. Magnesium diisopropyl amide has been used to prepare kinetic silyl enol ethers in virtual quantitative yield.[320] Reaction with Me_3SiCl/KI in DMF gives primarily the thermodynamic silyl enol ether.[321] The reaction of an unsymmetrical ketone with Mg and TMSCl in DMF gives a roughly 2:1 mixture of thermodynamic: kinetic silyl enol ether.[322]

An interesting synthesis of silyl enol ethers involves chain extension of an aldehyde. Aldehydes are converted to the silyl enol ether of a ketone upon reaction with lithium (trimethylsilyl)diazomethane and then a dirhodium catalyst.[323] Initial reaction of lithium(trimethylsilyl)diazomethane [LTMSD, prepared *in situ* by reaction of butyllithium with (trimethylsilyl)diazomethane] to the aldehyde (e.g., **37**) gave the alkoxide addition product. Protonation, and then capture by a transition-metal catalyst, and a 1,2-hydride migration gave the silyl enol ether, **38**.

37 38

Enol acetates are generally prepared by the reaction of an enolate anion with a suitable acylating reagent.[324] Enolate anions react with acyl halides and with anhydrides to give the acylated product. Both *C*-acylation and *O*-acylation are possible, but in general *O*-acylation predominates.[325] Note that the extent of *O*- versus *C*-acylation is very dependent on the local environment and electronic effects within the enolate anion.[326] Silyl sulfonate esters can be prepared by similar methods, using sulfonic acid anhydrides rather than carboxylic anhydrides. A polymer-supported triflating agent was used to prepare silyl enol triflate from ketones, in the presence of diisopropylethylamine.[327]

When a silyl enol ether is the trimethylsilyl derivative (Me_3Si–O-C=C), treatment with methyllithium will regenerate the lithium enolate anion and the volatile trimethylsilane (Me_3SiH).[328] The enolate anion can be used in the usual reactions. In a similar reaction, a trimethylsilyl enol ether was treated with Cp_2Zr (from Cp_2ZrCl_2/2 BuLi/THF/–78°C), and subsequent quenching with D_2O led to incorporation of deuterium at the vinyl carbon (C=C–D).[329]

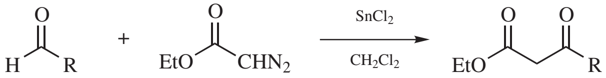
12-18 Conversion of Aldehydes to β-Keto Esters or Ketones

Alkoxycarbonylalkylation or **Alkoxycarbonylalkyl-de-hydrogenation**



β-Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid, such as $SnCl_2$, BF_3, or $GeCl_2$.[331] The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the

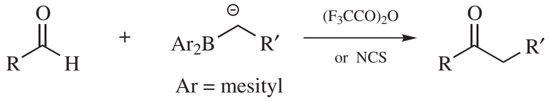
difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron, in the presence of $(F_3CCO)_2O$ or NCS, to give ketones.[332]

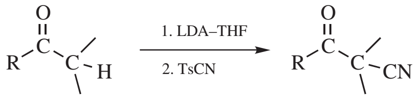


Ketones can be prepared from aryl aldehydes (ArCHO) by treatment with a rhodium complex $(Ph_3P)_2Rh(CO)Ar'$, whereby the Ar group is transferred to the aldehyde, producing the ketone, Ar–CO–Ar′.[333] In a rhodium catalyzed reaction, aryl aldehydes (ArCHO) react with Me_3SnAr' to give the diaryl ketone Ar–CO–Ar′.[334]

12-19 Cyanation or Cyano-de-hydrogenation

There are several reactions in which a C–H unit is replaced by C–CN. In virtually all cases, the hydrogen being replaced is on a carbon α to a heteroatom or functional group. There are several examples.

Introduction of a cyano group α to the carbonyl group of a ketone can be accomplished by prior formation of the enolate anion with LDA in THF and addition of this solution to *p*-TsCN at −78°C.[335] The products are formed in moderate to high yields but the reaction is not applicable to methyl ketones. Treatment of $TMSCH_2N(Me)C{=}Nt$-Bu with *sec*-butyllithium and $R_2C{=}O$, followed by iodomethane and NaOMe leads to the nitrile, R_2CH–CN.[336]



Cyanation has been shown to occur α to a nitrogen, specifically in *N,N*-dimethylaniline derivatives. Treatment with a catalytic amount of $RuCl_3$ in the presence of oxygen and NaCN leads to the corresponding cyanomethylamine.[337]

In a different kind of reaction, nitro compounds are α-cyanated by treatment with ^{-}CN and $K_3Fe(CN)_6$.[338] The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to α-cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me_3SiCN.[339] The compound Me_3SiCN has also been used in a reaction that cyanates benzylic positions.[340]

12-20 Alkylation of Alkanes

Alkylation or **Alkyl-de-hydrogenation**

$$RH + R'^{+} \longrightarrow R{-}R' + H^{+}$$

Alkanes can be alkylated by treatment with solutions of stable carbocations[341] (p. 235), but the availability of such carbocations is limited and mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate (Me_2C^{+} SbF_6–) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by **12-47**), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange ($RH + R'^{+}$ $R^{+} + R'H$) is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *tert*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH_3F or C_2H_5F and SbF_5.[342] The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with superacids, **12-1**) as

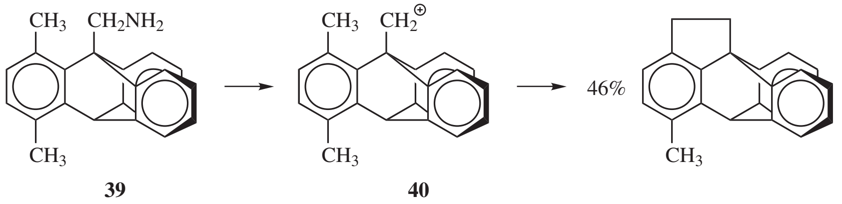
It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *tert*-butyl cations in superacid solutions (p. 236).[343]



Intramolecular insertion has been reported. The positively charged carbon of the carbocation **40**, generated from the diazonium salt of the triptycene compound **39**, reacted with the CH_3 group in close proximity with it.[344]

12-21 Insertion by Carbenes

***CH*-Methylene-insertion**

$$RH + :CH_2 \longrightarrow RCH_3$$

The highly reactive species methylene ($:CH_2$) inserts into C–H bonds,[345] both aliphatic and aromatic,[346] although with aromatic compounds subsequent ring expansion is also possible (see **15-64**). This is effectively a homologation reaction.[347] The methylene insertion reaction has limited utility because of its nonselectivity (see p. 284). The insertion reaction of carbenes has been used for synthetic purposes.[348] The carbenes can be generated in any of the ways mentioned in Chapter 5 (p. 287). Alkylcarbenes usually rearrange rather than give

insertion (p. 291), but, when this is impossible, *intramolecular* insertion[349] is found rather than intermolecular.[350] Methylene ($:CH_2$) generated by photolysis of diazomethane (CH_2N_2) in the liquid phase is indiscriminate (totally nonselective) in its reactivity (p. 288). Methylene ($:CH_2$) generated in other ways and mono-alkyl and dialkyl carbenes are less reactive and insert in the order tertiary > secondary > primary.[351] Carbene insertion with certain allylic systems can proceed with rearrangement of the double bond.[352] Carbenes have been generated in the presence of ultrasound.[353] Halocarbenes ($:CCl_2$, $:CBr_2$, etc.) insert much less readily, although a number of instances have been reported.[354] Insertion into the O–H bond of alcohols, to produce ethers, has been reported using a diazocarbonyl compound and an $In(OTf)_3$ catalyst.[355]

For the similar insertion reaction of nitrenes, see **12-13**.

The metal carbene insertion reaction, in contrast to the methylene insertion reaction, can be highly selective,[356] is very useful in synthesis,[357] and there are numerous examples, usually requiring a catalyst.[358] The catalyst typically convert a diazoalkane or diazocarbonyl compound to the metal carbene *in situ*, allowing the subsequent insertion reaction. Intermolecular reactions are known, including diazoalkane insertion reaction with a dirhodium catalyst.[359] When chiral ligands are present good enantioselectivity is observed in the insertion product.[360] Insertion at an allylic carbon of alkenes has been reported.[361] Insertion into a 2-pyrrolidinone derivative using $Me_3SiCH_2N_2$ followed by $AgCO_2Ph$ with ultrasound gave a

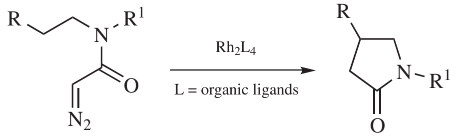
2-piperidone derivative.[362] The copper-catalyzed insertion of a diazo ester into an oxetane gives the ring-expanded tetrahydrofuran derivative.[363] Dirhodium catalyzed insertion into H–C^{sp2} bonds is also known,[364] and also H–C^{sp} bonds.[365] Insertion of diazoalkane and diazocarbonyl compounds can be catalyzed by copper compounds[366] and silver compounds[367] as well. Intramolecular insertion reactions are well known, and tolerate a variety of functional groups.[368] Intramolecular insertion at the α-carbon of a ketone by a diazoketone, using $TiCl_4$, gives a bicyclic 1,3-diketone.[369] A typical example is the insertion of the diazocarbonyl unit into the C–H bond to give the lactam.[370] Similar insertion at the α-carbon of an ether leads to cyclic ethers, with high enantioselectivity when a chiral ligand is used with a rhodium catalyst.[371] Similar insertion at the α-carbon of silyl ethers has been reported.[372] Aryl ketenes react with Me_3SiCHN_2 and then silica to give 2-indanone derivatives.[373]



The mechanism[374] of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

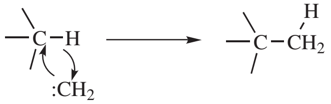
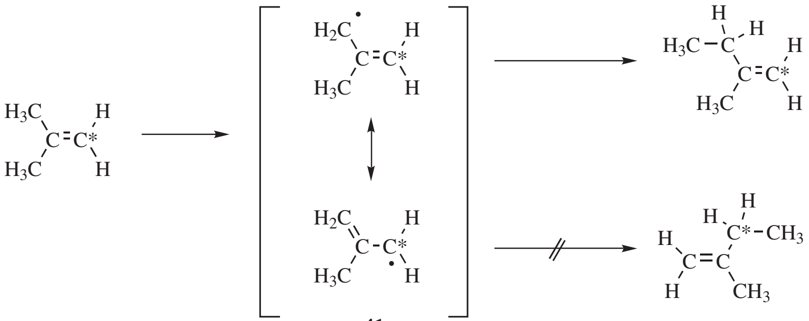
1. A simple one-step process involving a three-center cyclic transition state:



The most convincing evidence for this mechanism is that in the reaction between isobutene-1-^{14}C and carbene the product 2-methyl-1-butene was labeled only in the 1 position.[375] This rules out a free radical or a carbocation or carbanion intermediate. If **41** (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the 1 position:



41

Not found

Other evidence is that retention of configuration, which is predicted by this mechanism, has been found in a number of instances.[376] An ylid intermediate was trapped in the reaction of :CH_2 with allyl alcohol.[377]

2. A free-radical process in which the carbene directly abstracts a hydrogen from the substrate to generate a pair of free radicals:

$$\mathrm{RH} + \mathrm{CH_2} \longrightarrow \mathrm{R}\bullet + \bullet\mathrm{CH_3}$$
$$\mathrm{R}\bullet + \bullet\mathrm{CH_3} \longrightarrow \mathrm{RCH_3}$$

One fact supporting this mechanism is that among the products obtained (beside butane and isobutane) on treatment of propane with CH_2 (generated by photolysis of diazomethane and ketene) were propene and ethane,[378] which could arise, respectively, by

$$2\ \mathrm{CH_3CH_2CH_2}\bullet \longrightarrow \mathrm{CH_3CH{=}CH_2} + \mathrm{CH_3CH_2CH_3} \quad \text{(disproportionation)}$$

[378]Frey, H.M. *Proc. Chem. Soc.* ***1959***, 318.

and

$$CH_3CH_2CH_3 + :CH_2 \longrightarrow CH_3CH_2CH_2\bullet + \bullet CH_3$$
$$2\bullet CH_3 \longrightarrow CH_3CH_3$$

That this mechanism can take place under suitable conditions has been demonstrated by isotopic labeling[379] and by other means.[380] However, the formation of disproportionation and dimerization products does not always mean that the free-radical abstraction process takes place. In some cases, these products arise in a different manner.[381] We have seen that the product of the reaction between a carbene and a molecule may have excess energy (p. 288). Therefore it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction.

The mechanism of cyclopropylcarbene reactions has also been discussed.[382] It has been suggested[383] that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free-radical process. In support of this suggestion is that CIDNP signals[384] (p. 269) were observed in the ethylbenzene produced from toluene and triplet CH_2, but not from the same reaction with singlet CH_2.[385] Carbenoids (e.g., compounds of the form R_2CMCl, see **12-39**) can insert into a C–H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.[386]

An interesting insertion reaction involves $EtZnCH_2I$ and β-keto carbonyl compounds. The reaction of this reagent with *N,N*-dibutyl-**3**-oxobutanamide, for example, gives the methylene insertion product *N,N*-dibutyl 4-oxopentanamide.[387]

The reaction in which aldehydes are converted to methyl ketones, $RCHO + CH_2N_2 \rightarrow RCOCH_3$, while apparently similar, does not involve a free carbene intermediate. It is considered in Chapter 18 (**18-9**).

F. Metal Electrophiles

12-22 Metalation With Organometallic Compounds

Metalation or **Metalo-de-hydrogenation**

$$RH + R'M \longrightarrow RM + R'M$$

Many organic compounds can be metalated by treatment with an organometallic compound.[388] Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid.[389] For example, fluorene reacts with butyllithium to give butane and 9-fluoryllithium. Since aromatic hydrocarbons are usually stronger acids than aliphatic ones, R is most often aryl. The most common reagent is butyllithium.[390] Normally, only active aromatic rings react with butyllithium. Benzene itself reacts very slowly and in low yield, although benzene can be metalated by butyllithium either in the presence of *t*-BuOK[391] or by *n*-butyllithium that is coordinated with various diamines.[392] Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,[393] etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Very good reagents for allylic metalation are trimethylsilylmethyl potassium Me_3SiCH_2K[394] and a combination of an organolithium compound with a bulky alkoxide (LICKOR superbase).[395] The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.[396] In certain cases, *gem*-dialkali metal or 1,1,1-trialkali metal compounds can be prepared.[397] Examples are the conversion of phenylacetonitrile

to 1,1-dilithiophenylacetonitrile ($PhCLi_2CN$)[398] and propyne to tetralithiopropyne ($Li_3CC{\equiv}CLi$)[399] in each case by treatment with excess butyllithium. The reaction can be used to determine relative acidities of very weak acids by allowing two R–H compounds to compete for the same R′M and to determine which proton in a molecule is the most acidic.[400]

In general, the reaction can be performed only with organometallics of active metals such as lithium, sodium, and potassium, but Grignard reagents abstract protons from a sufficiently acidic C–H bond, as in R–C≡C–H → R–C≡C–MgX. This is the best method for the preparation of alkynyl Grignard reagents.[401]

When a heteroatom, such as N, O, S,[402] or a halogen,[403] is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.[404] The lithium usually bonds with the sp^2 carbon closest to the heteroatom, probably because the attacking species coordinates with the heteroatom.[405] Such reactions with compounds such as anisole are often called directed metalations.[406] In the case of aromatic rings this means attack at the ortho position,[407] but this is considered in **13-17**.

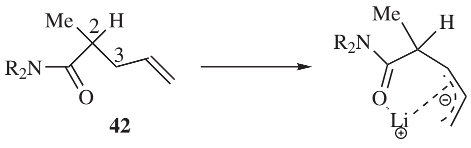
In the case of γ,δ-unsaturated disubstituted amides (**42**),the lithium does not go to the closest position, but in this case too the regiochemistry is controlled

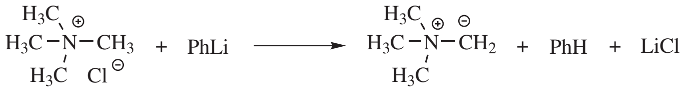


by coordination to the oxygen.[409]

The mechanism involves an attack by R′− (or a polar R′) on the *hydrogen*[410] (an acid–base reaction) Evidence is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and CF_3 *both* direct ortho, while isopropyl directs meta and para (mostly meta).[411] These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.[412] The nature of R′ also has an effect on the rate. In the reaction between triphenylmethane and R′Li, the rate decreased in the order R′ = allyl > Bu > Ph > vinyl > Me, although this order changed with changing concentration of R′Li, because of varying degrees of aggregation of the R′Li.

With respect to the reagent, this reaction is a special case of **12-24**.

A closely related reaction is formation of nitrogen ylids[414] from quaternary ammonium salts (see **17-8**):



Phosphonium salts undergo a similar reaction (see **16-44**).

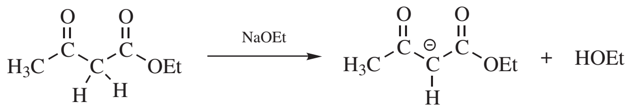
12-23 Metalation With Metals and Strong Bases

Metalation or **Metalo-de-hydrogenation**

$$2\ RH + M \longrightarrow 2\ RM + H_2$$

Organic compounds can be metalated at suitably acidic positions by active metals and by strong bases.[415] The reaction has been used to study the acidities of very weak acids (see p. 250). The conversion of terminal alkynes to acetylid ions is one important application.[416] Synthetically, an important use of the method is to convert aldehydes and ketones,[417] carboxylic esters, and similar compounds to their enolate forms,[418] for example,



for use in nucleophilic substitutions (**10-67**, **10-68**, and **13-14**) and in additions to multiple bonds (**15-24** and **16-53**). It has been shown that lithiation with lithium amides can also be regioselective (see **12-22**).[419] Lithium enolates exist as aggregates in solution.[420] For very weak acids, the most common reagents for synthetic purposes are lithium amides, especially LDA, which has the structure $(i\text{Pr})_2\text{NLi}$.[421] The mechanism for this deprotonation reaction has been studied,[422] as has the rate of deprotonation.[423]

METALS AS LEAVING GROUPS

A. Hydrogen as the Electrophile

12-24 Replacement of Metals by Hydrogen

Hydro-de-metallation or **Demetallation**

$$RM + HA \longrightarrow RH + MA$$

Organometallic compounds, including enolate anions, react with acids in reactions in which the metal is replaced by hydrogen.[424] The R group may be aryl (see **11-41**). The reaction is often used to introduce deuterium or tritium into susceptible positions. For Grignard reagents, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process RX → RMgX → RH.

Other organometallic compounds that are hydrolyzed by water are those of sodium, potassium, lithium, zinc, and so on, the ones high in the electromotive series. Enantioselective protonation of lithium enolates[425] and cyclopropyllithium compounds[426] have been reported. When the metal is less active, stronger acids are required. For example, R_2Zn compounds react explosively with water, R_2Cd slowly, and R_2Hg not at all, although the latter can be cleaved with concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example, BR_3 compounds are completely inert to water, and GaR_3 at room temperature cleave just one R group, but AlR_3 react violently with water. However, BR_3 can be converted to RH with carboxylic acids.[427] For less active metals it is often possible to cleave just one R group from a multivalent metal. For example,

$$R_2Hg + HCl \longrightarrow RH + RHgCl$$

Organometallic compounds of less active metals and metalloids (e.g., silicon,[428] antimony, and bismuth, are quite inert to water. Organomercury compounds (RHgX or R_2Hg) can be reduced to RH by H_2, $NaBH_4$, or other reducing agents.[429] The reduction with $NaBH_4$ takes place by a free-radical mechanism.[430] Alkyl–Si

bonds can be cleaved by H_2SO_4, for example, $HOOCCH_2CH_2SiMe_3 \rightarrow 2\ CH_4 + (HOOCCH_2CH_2SiMe_2)_2O$.[431]

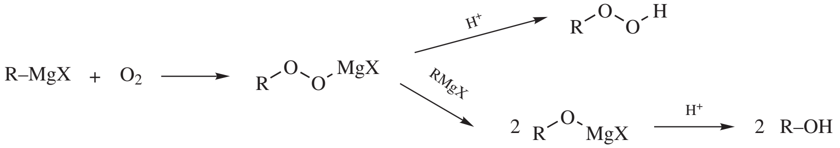
When the hydrogen of the HA is attached to carbon, this reaction is the same as **12-22**.

We do not list the many hydrolyses of sodium or potassium enolates, and so on found in *Organic Syntheses*. The hydrolysis of a Grignard reagent to give an alkane is found at OS **II**, 478; the reduction of a vinylic tin compound at OS **VIII**, 381; and the reduction of an alkynylsilane at OS **VIII**, 281.

B. Oxygen Electrophiles

12-25 The Reaction between Organometallic Reagents and Oxygen[432]

Hydroperoxy-de-metalation; Hydroxy-de-metalation



Oxygen reacts with Grignard reagents to give either hydroperoxides[433] or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents yields are lower and only phenols are obtained, not hydroperoxides. Because of this reaction, oxygen should be excluded when Grignard reagents are prepared and used in various reactions.

Most other organometallic compounds also react with oxygen. Trialkylboranes and alkyldichloroboranes $RBCl_2$ can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.[434] Dilithiated carboxylic acids (see **10-70**) react with oxygen to give (after hydrolysis) α-hydroxy carboxylic acids.[435] There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.[436]

The 1,1-dimetallic compounds $R_2C(SnMe_3)ZnBr$ were oxidized by dry air at -10 to 0°C in the presence of Me_3SiCl to give aldehydes or ketones $R_2C{=}O$.[437]

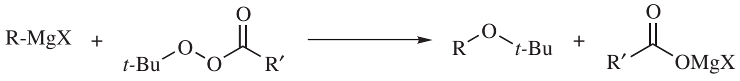
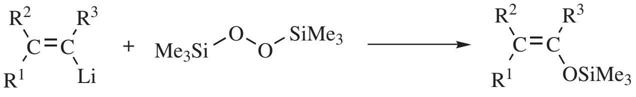
12-26 Reaction between Organometallic Reagents and Peroxides

tert-But**oxy-de-metalation**



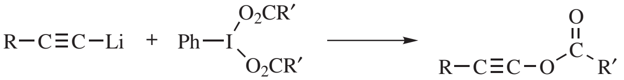
A convenient method of preparation of *tert*-butyl ethers consists of treating Grignard reagents with *tert*-butyl acyl peroxides.[438] Both alkyl and aryl Grignard reagents can be used. The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *tert*-butyl ethers of cyclopropanols,[439] which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by **10-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinylic lithium reagents (**43**) react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.[440] Since the preparation of **43** from vinylic halides



43

(**12-39**) also proceeds with retention, the overall procedure is a method for the stereospecific conversion of a vinylic halide to a silyl enol ether. In a related reaction, alkynyl esters can be prepared from lithium acetylides and phenyliodine(III) dicarboxylates.[441]



OS **V**, 642, 924.

12-27 Oxidation of Trialkylboranes to Borates

$$R_3B \xrightarrow[\text{NaOH}]{H_2O_2} (RO)_3B \longrightarrow 3\ ROH + B(OH)_3$$

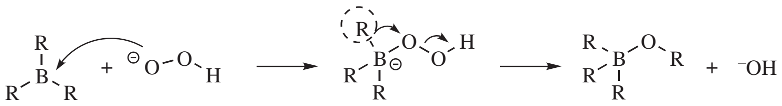
The reaction of alkenes with borane, monoalkyl and dialkylboranes leads to a new organoborane (see **15-16**). Treatment of organoboranes with alkaline H_2O_2 oxidizes trialkylboranes to esters of boric acid.[442] This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles that may be present elsewhere in the molecule. There is no rearrangement of the R group itself, and this reaction is a step in the hydroboration method of converting alkenes to alcohols (**15-16**). The mechanism has been formulated as involving initial formation of an ate complex when the hydroperoxide anion attacks the electrophilic boron atom. Subsequent rearrangement from boron to oxygen,[442] as shown, leads to the B–O–R unit.



Similar migration of the other two R groups and hydrolysis of the B–O bonds leads to the alcohol and boric acid. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,[443] with sodium perborate $NaBO_3$,[444] and with trimethylamine oxide, either anhydrous[445] or in the form of the dihydrate.[446] The reaction with oxygen is free radical in nature.[447]

OS **V**, 918; **VI**, 719, 852, 919.

12-28 Preparation of Borates and Boronic Acids

$$\text{R-M} \longrightarrow \text{R-B(OH)}_2$$

$$\text{Ar-M} \longrightarrow \text{Ar-B(OH)}_2$$

$$\text{R-OH} + \text{BX}_3 \text{ or B(OH)}_3 \longrightarrow \text{B(OR)}_3$$

Alkylboronic acids and arylboronic acids, $RB(OH)_2$, and $ArB(OH)_2$, respectively, are increasingly important in organic chemistry. The palladium catalyzed coupling reaction of aryl halides and aryl triflates with arylboronic acids (the Suzuki–Miyaura

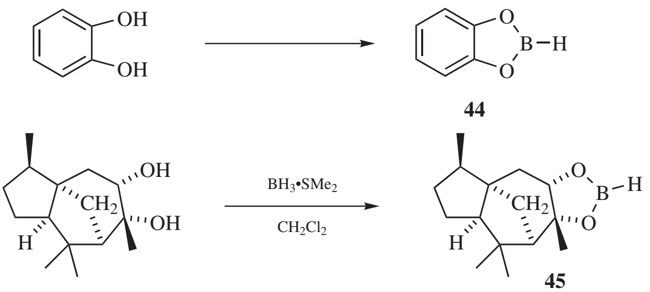
reaction, **13-12**) is probably the most notable example. A simple synthesis involve the reaction of a Grignard reagent, such as phenylmagnesium bromide with an alkyl borate to give phenylboronic acid.[448] Alkylboronic acids are similarly prepared.[449] Note that boronic acids are subject to cyclic trimerization with loss of water to form boroxines. Trimethylborate, $B(OMe)_3$, can be used in place of tri-*n*-butyl borate.[450] Newer methods involve the palladium-mediated borylation of alcohols with bis(pinacolato)diboron[451] or pinacolborane,[452] but deprotection of the boronate esters can be a problem. Diolboranes, such as catecholborane **44**,[453] are prepared by the reaction of a diol with borane. Cedranediolborane (**45**, prepared from the cedrane-8,9-diol[454] by treatment with borane•dimethyl sulfide) can be coupled to aryl iodides with a palladium catalyst, and generates the free boronic acid by treatment with diethanolamine and then aqueous acid.[455] Boronate esters are often prepared as a means to purify the organoboron species, but some of these esters are hydrolytically unstable and difficult to deal with upon completion of the reaction.[456]



44

45

Alkeneboronic esters and acids are also readily available, as in the addition of vinylmagnesium chloride[457] to trimethyl borate below −50°C, followed by hydrolysis.[458]

A nonaqueous workup procedure has been reproted for the preparation of arylboronic esters [ArB(OR'$_2$)].[459] Uncontrollable polymerization or oxidation of much of the boronic acid occurred during the final stages of the isolation procedure, but could be avoided by *in situ* conversion to the dibutyl ester by adding the crude product to 1-butanol. The samarium(III)-catalyzed hydroboration of olefins with catecholborane is a good synthesis of boronate esters.[460]

Trialkyl borates (called orthoborates) can be prepared by heating the appropriate alcohol with boron trichloride in a sealed tube, but the procedure works well only for relatively simple alkyl groups.[461] Heating alcohols with boron trioxide (B_2O_3) in an autoclave at 110–170°C give the trialkyl borate.[462] Boric acid can be used for the preparation of orthoborates[463] by heating with alcohols in the presence of either hydrogen chloride or concentrated sulfuric acid. Removal of water as an azeotrope with excess alcohol improves the yield,[464] and good yields can be obtained for trialkyl borates[465] and even for triphenyl borate.[466] This method is unsuccessful for those borates whose parent alcohols do not form azeotropes with water and for the tertiary alkyl borates,[467] impure samples are usually obtained.[468]

Potassium organotrifluoroborates (RBF_3K) are readily prepared by the addition of inexpensive KHF_2 to a variety of organoboron intermediates.[469] They are monomeric, crystalline solids that are readily isolated and indefinitely stable in the air. These reagents can be used in several of the applications where boronic acids or esters are used (**13-10–13-13**).[470] Note that vinylboronic acid and even vinylboronate esters are unstable to polymerization,[471] whereas the analogous vinyltrifluoroborate is readily synthesized and completely stable.[472]

sulfides,[478] and with SO_2 to give sulfinic acid salts[479] which can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.[480]

OS **III**, 771; **IV**, 667; **VI**, 533, 979.

D. Halogen Electrophiles

12-31 Halo-de-metalation

$$RMgX + I_2 \longrightarrow RI + MgIX$$

Grignard reagents react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl_2 to give mostly RBr and RI, respectively.[481]

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.[482] The reaction can be used to convert acetylide ions to 1-haloalkynes.[483] Since acetylide ions are easily prepared from alkynes (**12-23**), this provides a means of accomplishing the conversion $RC{\equiv}CH \rightarrow RC{\equiv}CX$. Vinyliodonium tetrafluoroborates were converted to vinyl fluorides by heating.[484] Similarly, vinyl trifluoroborates were converted to the vinyl iodide with NaI and chloramine-T in aq. THF.[485] The reaction of an alkene with CuO•BF4, iodine and triethylsilane gave the 2-iodo alkane.[486]

Trialkylboranes react rapidly with I_2[487] or Br_2[488] in the presence of NaOMe in methanol, or with $FeCl_3$ or other reagents[489] to give alkyl iodides, bromides, or chlorides, respectively. Combined with the hydroboration reaction (**15-16**), this is an indirect way of adding HBr, HI, or HCl to a double bond to give products with an

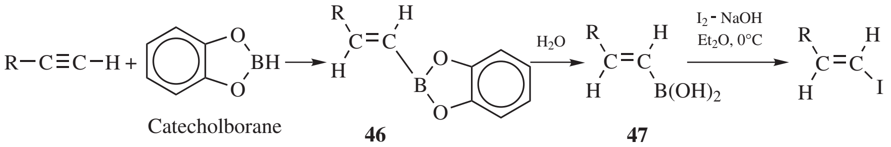
anti-Markovnikov orientation (see **15-1**). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free-radical process.[490] *trans*-1-Alkenylboronic acids **47**, prepared by hydroboration of terminal alkynes with catecholborane to give **46**[491] (**15-16**), followed by hydrolysis, react with I_2 in the presence of NaOH at 0°C in ethereal solvents to give trans vinylic iodides.[492] Treatment with ICl also gives the vinyl iodide.[493] This is an indirect way of accomplishing the anti-Markovnikov addition of HI to a



terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes. However, alkenylboronic acids prepared from both internal and terminal alkynes react with Br_2 (2 equivalents of Br_2 must be used) followed by base to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the cis vinylic bromide.[494] Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.[495] Treatment of **47** (prepared from terminal alkynes) with Cl_2 gave vinylic chlorides with inversion.[496] Vinylic boranes can be converted to the corresponding vinylic halide by treatment with NCS or NBS.[497] Vinylic halides can also be prepared from vinylic silanes[498] and from vinylic copper reagents. The latter react with I_2 to give iodides,[499] and with NCS or NBS at −45°C to give chlorides or bromides.[500] T

For the reaction of lithium enolate anions of esters with I_2 or CX_4, see **12-5**.

The conversion of terminal alkynes to 1-iodo-1-alkynes was reported using NaI under electrochemical conditions.[501] The reaction of an aryl alkyne with $HInCl_2/BEt_3$,

and then iodine leads to a *Z*-vinyl iodide with respect to the aryl group and the iodine atom.[502] 1-Bromo-1-alkynes were converted to the 1-iodo-1-alkyne with CuI.[503]

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.[504] In a number of cases, the reaction has been shown to involve inversion of configuration (see p. 757), indicating an S_E2 (back) mechanism, while in other cases retention of configuration has been shown,[505] implicating an S_E2 (front) or S_Ei mechanism. In still other cases, complete loss of configuration as well as other evidence have demonstrated the presence of a free-radical mechanism.[505,506]

E. Nitrogen Electrophiles

12-32 The Conversion of Organometallic Compounds to Amines

Amino-de-metalation

$$RLi \xrightarrow[MeLi]{CH_3ONH_2} RNH_2$$

There are several methods for conversion of alkyl- or aryllithium compounds to primary amines.[507] The two most important are treatment with hydroxylamine derivatives and with certain azides.[508] In the first of these methods, treatment of RLi with methoxyamine and MeLi in ether at −78°C gives RNH_2.[509] Grignard reagents from aliphatic halides give lower yields. The reaction can be extended to give secondary amines by the use of *N*-substituted methoxyamines (CH_3ONHR').[510] There is evidence[511] that the mechanism involves the direct displacement of OCH_3 by R

on an intermediate $CH_2ONR'^-$($CH_3ONR'^-$ Li^+ + RLi → CH_3OLi + RNR'^- Li^+). The most useful azide is tosyl azide TsN_3.[512] The initial product is usually RN_3, but this is easily reducible to the amine (**19-51**). With some azides, such as azidomethyl phenyl sulfide ($PhSCH_2N_3$), the group attached to the N_3 is a poor leaving group, so the initial product is a triazene (in this case $ArNHN{=}NCH_2SPh$ from ArMgX), which can be hydrolyzed to the amine.[513]

$$R_3B \xrightarrow{NH_3-NaOCl} 2\,RNH_2 + RB(OH)_2$$

Organoboranes react with a mixture of aqueous NH_3 and NaOCl to produce primary amines.[514] It is likely that the actual reagent is chloramine (NH_2Cl). Chloramine itself,[515] hydroxylamine-*O*-sulfonic acid in diglyme,[516] and trimethylsilyl azide[517] also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (**15-16**), this is an indirect method for the addition of NH_3 to a double bond with anti-Markovnikov orientation. Secondary amines can be prepared[518] by the treatment of alkyl- or aryldichloroboranes or dialkylchloroboranes with alkyl or aryl azides.

$$RBCl_2 + R'N_3 \longrightarrow RR'NBCl_2 \xrightarrow[OH^-]{H_2O} RNHR'$$

$$R_2BCl + R'N_3 \xrightarrow[2.H_2O]{1.Et_2O} RNHR'$$

The use of an optically active R^*BCl_2 gave secondary amines of essentially 100% optical purity.[519] Aryllead triacetates, $ArPb(OAc)_3$, give secondary amines (ArNHAr′) when treated with primary aromatic amines $Ar'NH_2$ and $Cu(OAc)_2$.[520]

Secondary amines have been converted to tertiary amines by treatment with lithium dialkylcuprate reagents: R_2CuLi + NHR → RNR_2'.[521] The reaction was also used to convert primary amines to secondary, but yields were lower.[522]

In the presence of a CuI catalyst, acetamide reacted with vinyl iodides to give the corresponding enamide, where the nitrogen of the amide replaced the iodine atom.[523]

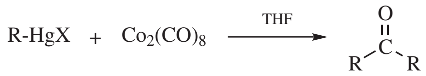
Terminal alkynes reacted with chlorodiphenylphosphine (Ph_2PCl) and a nickel catalyst to give the 1-diphenylphosphino alkyne (R-C≡C-PPh_2).[524] Alkynyl halides can be used for a similar reaction. Treatment of methyl carbamates with KHMDS and CuI, followed by two equivalents of 1-bromo phenylacetylene gave the *N*-substituted alkyne, Ph–C≡C–N(CO_2Me)R.[525]

OS **VI**, 943.

F. Carbon Electrophiles

12-33 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides

Acyl-de-metalation, and so on



Symmetrical ketones[526] can be prepared in good yields by the reaction of organomercuric halides[527] with dicobalt octacarbonyl in THF,[528] or with nickel carbonyl in DMF or certain other solvents.[529] The R group may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the $CO_2(CO)_8$ reaction, although the $Ni(CO)_4$ reaction seems to be free from such rearrangements.[530] Divinylic ketones (useful in the Nazarov cyclization, **15-20**) have been prepared in high yields by treatment of vinylic mercuric halides with CO and a rhodium catalyst.[530] In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds (R_4Sn) are treated with a halide R′X (R′ = aryl, vinylic, benzylic), CO, and a Pd complex catalyst.[531] Similar reactions use Grignard reagents, $Fe(CO)_5$, and an alkyl halide.[532] Cyclobutanone derivatives were prepared by carbonylation (treatment with CO) of a cyclic titanium compound.[533]

Grignard reagents react with formic acid to give good yields of aldehydes. Two equivalents of RMgX are used; the first converts HCOOH to HCOO–, which reacts

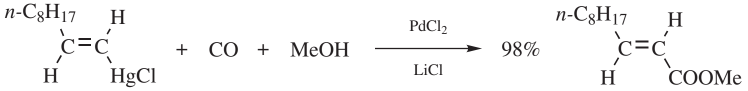
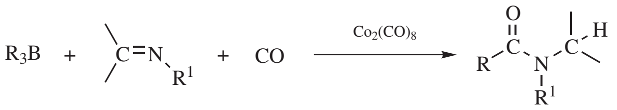
with the second equivalent to give RCHO.[534] Alkyllithium reagents and Grignard reagents react with CO to give symmetrical ketones.[535] An interesting variation reacts CO_2 with an organolithium, which is then treated with a different organolithium reagent to give the unsymmetrical ketone.[536] α,β-Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and $TiCl_4$ at −90°C.[537] α,β-Unsaturated esters can be prepared by treating boronic esters **27** with CO, $PdCl_2$, and NaOAc in MeOH.[538] The synthesis of α,β-unsaturated esters has also been accomplished by treatment of vinylic mercuric chlorides with CO at atmospheric pressure and a Pd catalyst in an alcohol as solvent, for example,[539]



Alkyl and aryl Grignard reagents can be converted to carboxylic esters with $Fe(CO)_5$ instead of CO.[540]

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl:[541]



In another method for the conversion RM → RCONR, Grignard reagents, and organolithium compounds are treated with a formamide ($HCONR_2'$) to give the intermediate $RCH(OM)NR_2'$, which is not isolated, but treated with PhCHO or Ph_2CO to give the product $RCONR_2'$.[542]

Direct conversion of a hydrocarbon to an aldehyde (R–H → R–CHO) was reported by treatment of the hydrocarbon with $GaCl_3$ and CO.[543]

12-34 Cyano-de-metalation

$$\text{R-M} + \text{CuCN} \longrightarrow \text{R-CN}$$

Vinylic copper reagents react with ClCN to give vinyl cyanides, although BrCN and ICN give the vinylic halide instead.[544] Vinylic cyanides have also been prepared by the reaction between vinylic lithium compounds and phenyl cyanate (PhOCN).[545] Alkyl nitriles (RCN) have been prepared, in varying yields, by treatment of sodium trialkylcyanoborates with NaCN and lead tetraacetate.[546] Vinyl bromides reacted with KCN, in the presence of a nickel complex and zinc metal to give the vinyl nitrile.[547] Vinyl triflates react with LiCN, in the presence of a palladium catalyst, to give the vinyl nitrile.[548]

For other electrophilic substitutions of the type RM → RC, which are discussed under nucleophilic substitutions in Chapter 10. See also, **16-81–16-85** and **16-99**.

G. Metal Electrophiles

12-35 Transmetallation With a Metal

Metalo-de-metalation

$$\text{RM} + \text{M}' \rightleftharpoons \text{RM}' + \text{M}$$

Many organometallic compounds are best prepared by this reaction, which involves replacement of a metal in an organometallic compound by another metal. The RM' compound can be successfully prepared only when M' is above M in the electromotive series, unless some other way is found to shift the equilibrium. That is, RM is usually an unreactive compound and M' is a metal more active than M. Most often, RM is R_2Hg, since mercury alkyls[527] are easy to prepare and mercury is far down in the electromotive series.[549] Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, and so on have been prepared this way. An important advantage of this method over **12-38** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.[550] If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

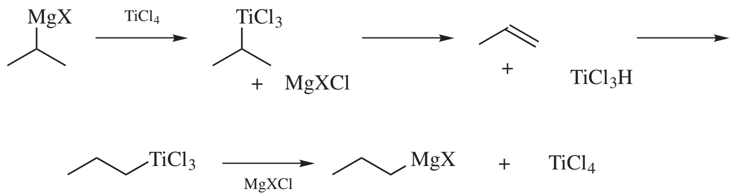
12-36 Transmetallation With a Metal Halide

Metalo-de-metalation

$$RM + M'X \rightleftharpoons RM' + MX$$

In contrast to **12-35**, the reaction between an organometallic compound and a metal *halide* is successful only when M' is *below* M in the electromotive series.[551] The two reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction, the most common substrates are Grignard reagents and organolithium compounds.[552]

The MgX of Grignard reagents[553] can migrate to terminal positions in the presence of small amounts of $TiCl_4$.[554] The proposed mechanism consists of metal exchange (**12-36**), elimination–addition, and metal exchange:



The addition step is similar to **15-16** or **15-17** and follows Markovnikov's rule, so the positive titanium goes to the terminal carbon.

Among others, alkyls of Be, Zn,[555] Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of Grignard reagents with the appropriate halide.[556] The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including

[551]For reviews of the mechanism, see Abraham, M.H.; Grellier, P.L. in Hartley, F.R.; Patai, S. *The Chemistry of the Carbon–Metal Bond*, Vol. 2, Wiley, NY, pp. 25–149; Abraham, M.H. *Comprehensive Chemical Kinetics*, Bamford, C.H.; Tipper, C.F.H., Eds., Vol. 12; Elsevier, NY, ***1973***, pp. 39–106; Jensen, F.R.; Rickborn, B. *Electrophilic Substituton of Organomercurials*, McGraw-Hill, NY, ***1968***, pp. 100–192. Si, B,[557] Ge, P, As, Sb, and Bi, can also be prepared in this manner.[558] Except for alkali-metal alkyls and Grignard reagents, the reaction between RM and M′X is the most common method for the preparation of organometallic compounds.[559]

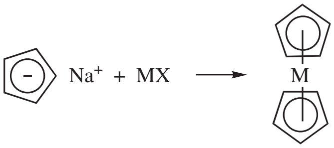
Lithium dialkylcopper reagents can be prepared by mixing 2 equivalents of RLi with 1 equivalent of a cuprous halide in ether at low temperatures:[560]

$$2\ RLi + CuX \longrightarrow R_2CuLi + LiX$$

Another way is to dissolve an alkylcopper compound in an alkyllithium solution. Higher order cuprates can also be prepared, as well as "non-ate" copper reagents.[561]

Metallocenes (**48**, see p. 66) are usually made by this method:



48

Among others, metallocenes of Sc, Ti, V, Cr, Mn, Fe, Co, and Ni have been prepared in this manner.[562]

Metal nitrates are sometimes used instead of halides.

In a related reaction sulfurated boranes (R_2B–$SSiR'_2$) react with Grignard reagents, such as methylmagneisum bromide to give the B-alkyl borane (e.g., R_2B–Me) upon heating *in vacuo*.[563]

12-37 Transmetalation With an Organometallic Compound

Metalo-de-metalation

$$\text{RM} + \text{R}'\text{M}' \rightleftharpoons \text{RM}' + \text{R}'\text{M}$$

This type of metallic exchange is used much less often than **12-35** and **12-36**. It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways,[564] for example, a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyllithium from phenyllithium and tetravinyltin and the formation of α-dialkylamino organolithium compounds from the corresponding organotin compounds[565]

$$\text{RR}'\text{NCH}_2\text{SnBu}_3 + \text{BuLi} \xrightarrow{0^\circ\text{C}} \text{RR}'\text{NCH}_2\text{Li} + \text{Bu}_4\text{Sn}$$

The reaction has also been used to prepare 1,3-dilithiopropanes[566] and 1,1-dilithiomethylenecyclohexane[567] from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (p. 250). The reaction proceeds with retention of configuration;[568] an S_Ei mechanism is likely.[569]

"Higher order" cuprates[570] (see **10-58**) have been produced by this reaction starting with a vinylic tin compound:[571]

$$\text{RSnR}'_3 + \text{Me}_2\text{Cu(CN)Li}_2 \longrightarrow \text{RCuMe(CN)Li}_2 + \text{MeSnR}'_{3-} \qquad \text{R} = \text{a vinylic group}$$

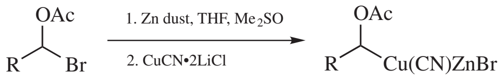
These compounds are not isolated, but used directly *in situ* for conjugate addition reactions (**15-25**). Another method for the preparation of such reagents (but with Zn instead of Li) allows them to be made from α-acetoxy halides:[572]



OS **V**, 452; **VI**, 815; **VIII**, 97.

HALOGEN AS LEAVING GROUP

The reduction of alkyl halides can proceed by an electrophilic substitution mechanism, but it is considered in Chapter 19 (**19-53**).

12-38 Metalo-de-halogenation

$$\text{RX} + \text{M} \longrightarrow \text{RM}$$

Alkyl halides react directly with certain metals to give organometallic compounds.[573] The most common metal is magnesium, and of course this is by far the most common method for the preparation of Grignard reagents.[574] The order of halide activity is I > Br > Cl. The reaction can be applied to many alkyl halides primary, secondary, and tertiary and to aryl halides, although aryl *chlorides* require the use of THF or another higher boiling solvent instead of the usual ether, or special entrainment methods.[575] Aryl iodides and bromides can be treated in the usual manner. Allylic Grignard reagents can also be prepared in the usual manner (or in THF),[576] although in the presence of excess halide these may give Wurtz-type coupling products (see **10-56**).[577] Like aryl chlorides, vinylic halides require higher boiling solvents (see OS **IV**, 258). A good procedure for benzylic and allylic halides is to use magnesium anthracene (prepared from Mg and anthracene in THF)[578]

instead of ordinary magnesium,[579] although activated magnesium turnings have also been used.[580] Alkynyl Grignard reagents are not generally prepared by this method at all. For these, **12-22** is used. Grignard reagents can also be formed from an alkyl halide and 1,2-dibromoethane with iodine as an initiator.[581]

Dihalides[582] can be converted to Grignard reagents if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain dimagnesium compounds (e.g., $BrMg(CH_2)_4MgBr$).[583] 1,2-Dihalides give elimination[584] instead of Grignard reagent formation (**17-22**), and the reaction is seldom successful with 1,1-dihalides, although the preparation of *gem*-disubstituted compounds, such as $CH_2(MgBr)_2$, has been accomplished with these substrates.[585] α-halo Grignard reagents and α-halolithium reagents can be prepared by the method given in **12-39**.[586] Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g., I_2 or EtBr) in THF for several days.[587] Nitrogen-containing Grignard reagents have been prepared.[588]

The presence of other functional groups in the halide usually affects the preparation of the Grignard reagent. Groups that contain active hydrogen (defined as any hydrogen that will react with a Grignard reagent), such as OH, NH_2, and COOH, can be present in the molecule, but only if they are converted to the salt form (O^-, NH^-, COO^-, respectively). Groups that react with Grignard reagents, such as C=O, C≡N, NO_2, COOR, inhibit Grignard formation entirely. In general, the only functional groups that may be present in the halide molecule without any interference at all are double and triple bonds (except terminal triple bonds) and OR and NR_2 groups. However, β-halo ethers generally give β elimination when treated with

magnesium (see **17-24**), and Grignard reagents from α-halo ethers[589] can only be formed in THF or dimethoxymethane at a low temperature, for example,[590]

$$EtOCH_2Cl + Mg \xrightarrow[-30°C]{THF\ or\ CH_2(OMe)_2} EtOCH_2MgCl$$

because such reagents immediately undergo a elimination (see **12-39**) at room temperature in ether solution.

Because Grignard reagents react with water (**12-24**) and with oxygen (**12-25**), it is generally best to prepare them in an anhydrous nitrogen atmosphere. Grignard reagents are generally neither isolated nor stored; solutions of Grignard reagents are used directly for the required synthesis. Grignard reagents can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the RMgX.[591] This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.[592] It is also possible to obtain Grignard reagents in powdered form, by complexing them with the chelating agent tris(3,6-dioxaheptyl)amine, $N(CH_2CH_2OCH_2CH_2OCH_3)_3$.[593]

Next to the formation of Grignard reagents, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium compounds,[594] but it has also been carried out with many other metals (e.g., Na, Be, Zn, Hg, As, Sb, and Sn). With sodium, the Wurtz reaction (**10-56**) is an important side reaction. In some cases where the reaction between a halide and a metal is too slow, an alloy of the metal with potassium or sodium can be used instead. The most important example is the preparation of tetraethyl lead from ethyl bromide and a Pb–Na alloy.

The efficiency of the reaction can often be improved by use of the metal in its powdered[595] or vapor[596] form. These techniques have permitted the preparation of some organometallic compounds that cannot be prepared by the standard

procedures. Among the metals produced in an activated form are Mg,[597] Ca,[598] Zn,[599] Al, Sn, Cd,[600] Ni, Fe, Ti, Cu,[601] Pd, and Pt.[602]

The mechanism of Grignard reagent formation involves free radicals,[603] and there is much evidence for this, from CIDNP[604] (p. 269) and from stereochemical, rate, and product studies.[605] Further evidence is that free radicals have been trapped,[606] and that experiments that studied the intrinsic reactivity of MeBr on a magnesium single-crystal surface showed that Grignard reagent formation does not take place by a single-step insertion mechanism.[607] The following SET mechanism has been proposed:[604]

$$R{-}X + \overline{Mg} \longrightarrow R{-}X^{\bullet -} + Mg_s^{\bullet +}$$
$$R{-}X^{\bullet -} \longrightarrow R^{\bullet} + X^{-}$$
$$X^{-} + Mg_s^{\bullet +} \longrightarrow XMg_s^{\bullet}$$
$$R^{\bullet} + XMg_s^{\bullet} \longrightarrow RMgX$$

Other evidence has been offered to support a SET-initiated radical process for the second step of this mechanism.[608] The species $R{-}X^{\bullet -}$ and $Mg^{\bullet +}$ are radical ions.[609] The subscript "s" is meant to indicate that the species so marked are bound to the surface of the magnesium. It is known that this is a surface reaction.[610] It has been suggested that some of the $R^{\bullet}$ radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the $XMg^{\bullet}$. There is evidence

both for[611] and against[612] this suggestion. Another proposal is that the fourth step is not the one shown here, but that the R• is reduced by Mg^+ to the carbanion R^-, which combines with MgX^+ to give RMgX.[613]

There are too many preparations of Grignard reagents in *Organic Syntheses* for us to list here. Chiral Grignard reagents are rare, since they are configurationally unstable in most cases. However, a few chiral Grignard reagents are known.[614] Use of the reaction to prepare other organometallic compounds can be found in OS **I**, 228; **II**, 184, 517, 607; **III**, 413, 757; **VI**, 240; **VII**, 346; **VIII**, 505. The preparation of unsolvated butylmagnesium bromide is described at OS **V**, 1141. The preparation of highly reactive (powdered) magnesium is given at OS **VI**, 845.

12-39 Replacement of a Halogen by a Metal from an Organometallic Compound

Metalo-de-halogenation

$$RX + R'M \longrightarrow RM + R'X$$

The exchange reaction between halides and organometallic compounds occurs most readily when M is lithium and X is bromide or iodide,[615] although it has been shown to occur with magnesium.[616] The R' group is usually, although not always, alkyl, and often butyl; R is usually aromatic.[617] Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give Wurtz coupling. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Despite the preponderance of reactions with bromides and iodides, it is noted that the reaction of 1-fluorooctane with 4–10 equivalents of lithium powder and 2–4 equivalents of DTBB (4,4′-di-*tert*-butylbiphenyl) in THP at 0°C for 5 min, was shown to give a solution of the corresponding 1-octyllithium.[618] Vinylic halides react with retention of configuration.[619] The

[619]For examples of exchange where R = vinylic, see Neumann, H.; Seebach, D. *Chem. Ber.* ***1978***, *111*, 2785; Miller, R.B.; McGarvey, G. *Synth. Commun.* ***1979***, *9*, 831; Sugita, T.; Sakabe, Y.; Sasahara, T.; Tsukuda, M.; Ichikawa, K. *Bull. Chem. Soc. Jpn.* ***1984***, *57*, 2319.

reaction can be used to prepare α-halo organolithium and α-halo organomagnesium compounds,[620] for example,[621]

$$CCl_4 + BuLi \xrightarrow[-105^\circ C]{THF} Cl_3C\text{—}Li$$

Such compounds can also be prepared by hydrogen–metal exchange, for example,[622]

$$Br_3CH + i\text{PrMgCl} \xrightarrow[-95^\circ C]{THF-HMPA} Br_3C\text{—}MgCl + C_3H_8$$

This is an example of **12-22**. However, these α-halo organometallic compounds are stable (and configurationally stable as well[623]) only at low temperatures (ca. -100°C) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures they lose MX (α elimination) to give carbenes (which then react further) or carbenoid reactions. The α-chloro-α-magnesio sulfones $ArSO_2CH(Cl)MgBr$ are exceptions, being stable in solution at room temperature and even under reflux.[624] Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.[625]

There is evidence that the mechanism[626] of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.[627]

$$RX + R'M \rightleftarrows \underset{\text{Solvent cage}}{[R\bullet, X, M, R'\bullet]} \rightleftarrows RM + R'X$$

Among the evidence is the fact that coupling and disproportionation products are obtained from R• and R′• and the observation of CIDNP.[627,628] However, in the degenerate exchange between PhI and PhLi the ate complex Ph_2I^- Li^+ has been

[620]For reviews of such compounds, see Siegel, H. *Top. Curr. shown to be an intermediate,[629] and there is other evidence that radicals are not involved in all instances of this reaction.[630]

In a completely different kind of process, alkyl halides can be converted to certain organometallic compounds by treatment with organometalate ions, for example,

$$RX + R'_3SnLi \longrightarrow RSnR'_3 + LiX$$

Most of the evidence is in accord with a free-radical mechanism involving electron transfer, although an S_N2 mechanism can compete under some conditions.[631]

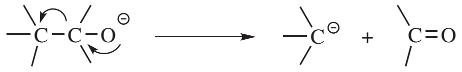
CARBON LEAVING GROUPS

In these reactions (**12-40–12-48**), a carbon–carbon bond cleaves. We regard as the substrate the side that retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (**12-42**) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,[632] although they do not always occur by mechanisms involving free carbanions (S_E1). When they do, the reactions are facilitated by increasing stability of the carbanion.

A. Carbonyl-Forming Cleavages

These reactions follow the pattern



The leaving group is stabilized because the electron deficiency at its carbon is satisfied by a pair of electrons from the oxygen. With respect to the leaving group the reaction is elimination to form a C=O bond. Retrograde aldol reactions (**16-34**) and cleavage of cyanohydrins (**16-52**) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in Chapter 17 (**17-32**).

12-40 Decarboxylation of Aliphatic Acids

Hydro-de-carboxylation

$$RCOOH \longrightarrow RH + CO_2$$

TABLE 12.2. Some Acids that Undergo Decarboxylation Fairly Readily[a]

	Acid Type	Decarboxylation Product
Malonic		α-Cyano		 or α-Nitro		α-Aryl		α,α,α-Trihalo	X_3C——COOH	X_3C–H
β-Keto		β,γ-Unsaturated		
[a]Others are described in the text.

Many carboxylic acids can be successfully decarboxylated, either as the free acid or in the salt form, but not simple fatty acids.[633] An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Malonic acid derivatives are the most common substrates for decarboxylation, giving the corresponding monocarboxylic acid. Decarboxylation of 2-substituted malonic acids has been reported using microwave irradiation.[634] Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the α or β position. Some of these are shown in Table 12.2. For decarboxylation of aromatic acids, see **11-35**. Decarboxylation of an α-cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.2, decarboxylation can also be carried out on α,β-unsaturated and α,β-acetylenic acids. α,β-Unsaturated acids can also be decarboxylated[635] with copper

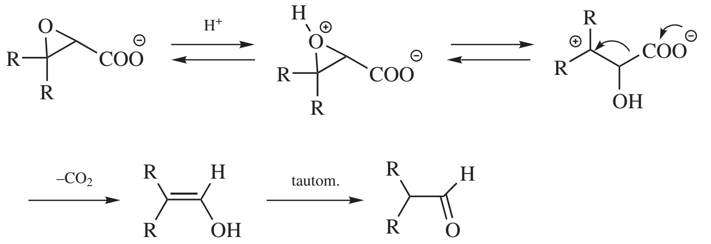
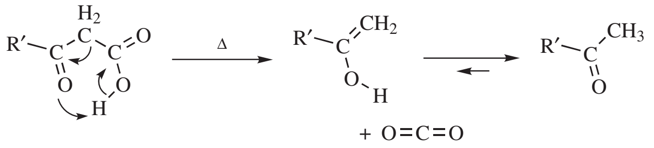
and quinoline in a manner similar to that discussed in **11-35**. Glycidic acids give aldehydes on decarboxylation. The following mechanism has been suggested:[636]



The direct product is an enol that tautomerizes to the aldehyde.[637] This is the usual last step in the Darzens reaction (**16-40**).

Decarboxylations can be regarded as reversals of the addition of carbanions to carbon dioxide (**16-82**), but free carbanions are not always involved.[638] When the carboxylate *ion* is decarboxylated, the mechanism can be either S_E1 or S_E2. In the case of the S_E1 mechanism, the reaction is of course aided by the presence of electron-withdrawing groups, which stabilize the carbanion.[639] Decarboxylations of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.[640] The reaction without the metallic ion has also been performed in the gas phase.[641] But some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:



Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of β-keto acids,[642] but it is likely that malonic acids, α-cyano acids, α-nitro acids, and β,γ-unsaturated acids[643] behave similarly,

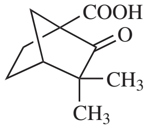
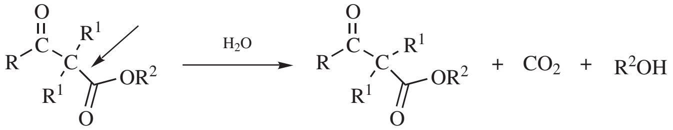
since similar six-membered transition states can be written for them. Some α,β-unsaturated acids are also decarboxylated by this mechanism by isomerizing to the β,γ-isomers before they



49

actually decarboxylate.[644] Evidence is that **49** and similar bicyclic β-keto acids resist decarboxylation.[645] In such compounds, the six-membered cyclic transition state cannot form for steric reasons, and if it could, formation of the intermediate enol would violate Bredt's rule (p. 229).[646] Some carboxylic acids that cannot form a six-membered transition state can still be decarboxylated, and these presumably react through an S_E1 or S_E2 mechanism.[647] Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water[648]), and is not subject to acid catalysis.[649] The rate of decarboxylation of a β,γ-unsaturated acid was increased $\sim 10^5$–10^6 times by introduction of a β-methoxy group, indicating that the cyclic transition state has dipolar character.[650]



β-Keto acids[651] are easily decarboxylated, but such acids are usually prepared from β-keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.[652] This decarboxylation of β-keto esters

involving cleavage on the carboxyl side of the substituted methylene group (arrow) is carried out under acidic, neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the CR_2 group (**12-43**). β-Keto esters can be decarbalkoxylated without passing through the free-acid stage by treatment with boric anhydride (B_2O_3) at 150°C.[653] The alkyl portion of the ester (R') is converted to an alkene or, if it lacks a β hydrogen, to an ether R'OR'. Another method for the decarbalkoxylation of β-keto esters, malonic esters, and α-cyano esters consists of heating the substrate in wet DMSO containing NaCl, Na_3PO_4, or some other simple salt.[654] In this method too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol. Ordinary carboxylic acids, containing no activating groups, can be decarboxylated by conversion to esters of *N*-hydroxypyridine-2-thione and treatment of these with Bu_3SnH.[655] A free-radical mechanism is likely. α-Amino acids have been decarboxylated by treatment with a catalytic amount of 2-cyclohexenone.[656] Amino acids are decarboxylated by sequential treatment with NBS at pH 5 followed by $NaBH_4$ and $NiCl_2$.[657] Certain decarboxylations can also be accomplished photochemically.[658] See also, the decarbonylation of acyl halides, mentioned in **14-32**. In some cases, decarboxylations can give organometallic compounds: $RCOOM \rightarrow RM + CO_2$.[659]

Some of the decarboxylations listed in *Organic Syntheses* are performed with concomitant ester or nitrile hydrolysis and others are simple decarboxylations.

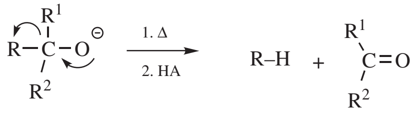
12-41 Cleavage of Alkoxides

Hydro-de-(α-oxidoalkyl)-substitution



Alkoxides of tertiary alcohols can be cleaved in a reaction that is essentially the reverse of addition of carbanions to ketones (**16-24**).[660] The reaction is unsuccessful when the R groups are simple unbranched alkyl groups, for example, the alkoxide of triethylcarbinol. Cleavage is accomplished with branched alkoxides, such as the alkoxides of diisopropylneopentylcarbinol or tri-*tert*-butylcarbinol.[661] Allylic,[662] benzylic,[663] and aryl groups also cleave; for example, the alkoxide of triphenylcarbinol gives benzene and benzophenone. Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.[664] However, with some substrates in solution, substantial amounts of dimer R–R have been found, indicating a radical pathway.[665] Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.[666]

The reaction has been used for extensive mechanistic studies (see p. 758).

OS **VI**, 268.

12-42 Replacement of a Carboxyl Group by an Acyl Group

Acyl-de-carboxylation

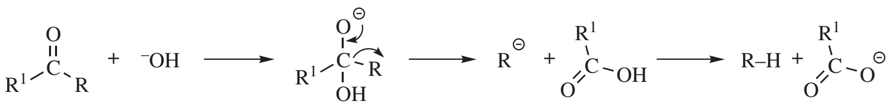
When an α-amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the NH_2 becomes acylated. This is called the *Dakin–West reaction*.[667] The mechanism involves formation of an oxazolone.[668] The reaction sometimes takes place on carboxylic acids even when an a amino group is not present. A number of *N*-substituted amino acids, RCH(NHR′)COOH, give the corresponding *N*-alkylated products.

OS **IV**, 5; **V**, 27.

B. Acyl Cleavages

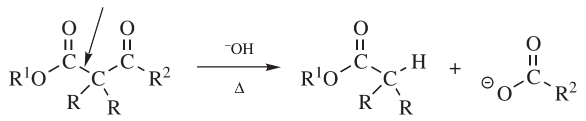
In these reactions (**12-43–12-46**), a carbonyl group is attacked by a hydroxide ion (or amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, this is nucleophilic substitution at a carbonyl group and the mechanism is the tetrahedral one discussed in Chapter 10.



With respect to R this is of course electrophilic substitution. The mechanism is usually S_E1.

12-43 Basic Cleavage of β-Keto Esters and β-Diketones

Hydro-de-acylation



When β-keto esters are treated with concentrated base, cleavage occurs, but is on the keto side of the CR_2 group (arrow) in contrast to the acid cleavage mentioned on page 838. The products are a carboxylic ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions. β-Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both β-keto esters and β-diketones, $^-$OEt can be used instead of $^-$OH, in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of β-keto esters, this is the reverse of Claisen condensation (**16-85**). The similar cleavage of cyclic α-cyano

[667]For a review, see Buchanan, G.L. *Chem. Soc. Rev.* ***1988***, *17*, 91.

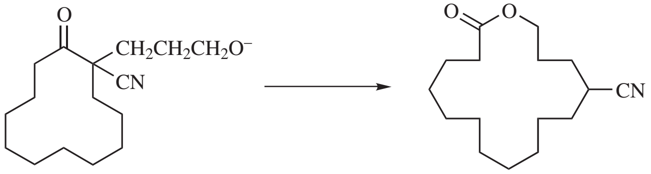
ketones, in an intramolecular fashion, has been used to effect a synthesis of macrocyclic lactones such as **50**.[669]

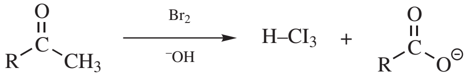


50

Activated F^- (from KF and a crown ether) has been used as the base to cleave an α-cyano ketone.[670]

OS **II**, 266, 531; **III**, 379; **IV**, 415, 957; **V**, 179, 187, 277, 533, 747, 767.

12-44 Haloform Reaction



In the *haloform reaction*, methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.[671] The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of **12-4**, in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion to give tetrahedral intermediate **51**.[672] The X_3C^- group is a sufficiently good leaving group (not HX_2C^- or H_2XC^-) that a carboxylic acid is formed, with quickly reacts with the carbanion to give the final products. Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed.

As with **12-4**, the rate-determining step is the preliminary enolization of the methyl ketone.[673] A side reaction is α halogenation of the non-methyl R group. Sometimes these groups are also cleaved.[674] The reaction cannot be applied to F_2, but ketones of the form $RCOCF_3$ (R = alkyl or aryl) give fluoroform and $RCOO^-$ when treated with base.[675] Rate constants for cleavage of X_3CCOPh (X = F, Cl, Br) were found to be in the ratio $1 : 5.3 \times 10^{10} : 2.2 \times 10^{13}$, showing that an F_3C^- group cleaves much more slowly than the others.[676] The haloform reaction is often used as a test for methylcarbinols and methyl ketones. Iodine is most often used as the test reagent, since iodoform (HCI_3) is an easily identifiable yellow solid. The reaction is also frequently used for synthetic purposes. Methyl ketones $RCOCH_3$ can be converted directly to methyl esters $RCOOCH_3$ by an electrochemical reaction.[677] Trifluoromethyl ketones have been converted to ethyl esters via treatment with NaH in aqueous DMF followed by reaction with bromoethane.[678]

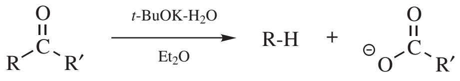
12-45 Cleavage of Nonenolizable Ketones

Hydro-de-acylation



Ordinary ketones are generally much more difficult to cleave than trihalo ketones or β-diketones, because the carbanion intermediates in these cases are more stable than simple carbanions. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of *t*-BuOK–H_2O in an aprotic solvent, such as ether, DMSO, 1,2-dimethoxyethane (glyme), [679] or with solid *t*-BuOK in the absence of a solvent.[680] When the reaction is applied to monosubstituted diaryl ketones, that aryl group preferentially cleaves that comes off as the more stable carbanion, except that aryl groups substituted in the ortho position are more readily cleaved than otherwise because of the steric effect (relief of strain).[680,681] In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.[682]

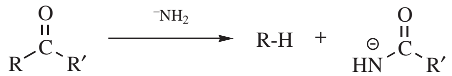
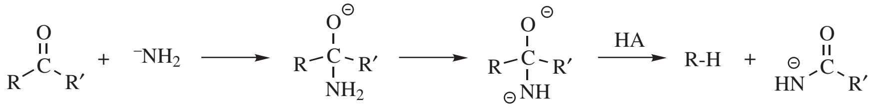
12-46 The Haller–Bauer Reaction

Hydro-de-acylation



Cleavage of ketones with sodium amide is called the *Haller–Bauer reaction*.[683] As with **12-45**, which is exactly analogous, the reaction is usually applied only to nonenolizable ketones, most often to ketones of the form $ArCOCR_3$, where the products R_3CCONH_2 are not easily attainable by other methods. However, many other ketones have been used, although benzophenone is virtually unaffected. It has been shown that the configuration of optically active alkyl groups (R) is retained.[684] The NH_2 loses its proton from the tetrahedral intermediate **52** before the R group is cleaved.[685]



52

An extension of this cleavage process involves the reaction of α-nitro ketones ($O{=}C\text{-}CHRNO_2$) with a primary amine, neat, to give the corresponding amide ($O{=}C\text{-}NHR'$).[686]

OS **V**, 384, 1074.

C. Other Cleavages

12-47 The Cleavage of Alkanes

Hydro-de-*tert*-butylation, and so on

$$(CH_3)_4C \xrightarrow{FSO_3H\text{-}SbF_5} CH_4 + (CH_3)_3C^+$$

The C–C bonds of alkanes can be cleaved by treatment with superacids[48] (p. 236). For example, neopentane in $FSO_3H–SbF_5$ can cleave to give methane and the *tert*-butyl cation. The C–H cleavage (see **12-1**) is a competing reaction and, for example, neopentane can give H_2 and the *tert*-pentyl cation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C–H $>$ C–C $>$ secondary C–H $\gg$ primary C–H,

[683]For a review, see Gilday, J.P.; Paquette, L.A. *Org. Prep. Proced. Int.* ***1990***, *22*, 167. For an improved procedure, see Kaiser, E.M.; Warner, C.D. *Synthesis* ***1975***, 395.

although steric factors cause a shift in favor of C–C cleavage in such a hindered compound as tri-*tert*-butylmethane. The mechanism is similar to that shown in **12-1** and **12-20** and involves attack by H^+ on the C–C bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated C–C bonds (i.e., $R{-}R' + H_2 \rightarrow RH + R'H$), but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni–Al_2O_3 catalyst at about 250°C.[687] Certain C–C bonds have been cleaved by alkali metals.[688]

The C–C bond of 2-allyl-2-arylmalonate derivatives was cleaved, with loss of the allylic group to give the 2-arylmalonate, by treatment with a nickel catalyst.[689]

12-48 Decyanation or Hydro-de-cyanation

$$\text{RCN} \xrightarrow{\text{Na-NH}_3 \text{ or Na-Fe(acac)}_3} \text{RH}$$

The cyano group of alkyl nitriles can be removed[690] by treatment with metallic sodium, either in liquid ammonia,[691] or together with tris(acetylacetonato)iron(III) [$Fe(acac)_3$][692] or, with lower yields, titanocene. The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na–NH_3 method gives high yields with R groups, such as trityl, benzyl, phenyl, and tertiary alkyl, but lower yields (~35–50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na–$Fe(acac)_3$ procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R• that would then be reduced to the carbanion R^-, which by abstraction of a proton from the solvent, would give RH. The mechanism with $Fe(acac)_3$ is presumably different. Another procedure,[693] which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.[694]

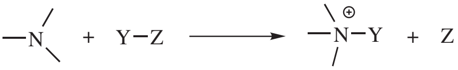
α-Amino and α-amido nitriles RCH(CN)NR'$_2$ and RCH(CN)NHCOR' can be decyanated in high yield by treatment with $NaBH_4$.[695]

ELECTROPHILIC SUBSTITUTION AT NITROGEN

In most of the reactions in this section, an electrophile bonds with the unshared pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:



53

Further reaction of **53** depends on the nature of Y and of the other groups attached to the nitrogen.

12-49 The Conversion of Hydrazines to Azides

Hydrazine–azide transformation

$$RNHNH_2 + HONO \longrightarrow R{-}\overset{\oplus}{N}{=}\overset{\ominus}{N}{=}N$$

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in **13-19**. Among other reagents used for this conversion have been N_2O_4[696] and nitrosyl tetrafluoroborate ($NOBF_4$).[697]

OS **III**, 710; **IV**, 819; **V**, 157.

12-50 *N*-Nitrosation

***N*-Nitroso-de-hydrogenation**

$$R_2NH + HONO \longrightarrow R_2N{-}NO$$

When secondary amines are treated with nitrous acid (typically formed from sodium nitrite and a mineral acid),[698] *N*-nitroso compounds (also called

[695]Yamada, S.; Akimoto, H. *Tetrahedron Lett.* ***1969***, 3105; Fabre, C.; Hadj Ali Salem, M.; Welvart, Z. *Bull. Soc. Chim. Fr.* ***1975***, 178. See also Ogura, K.; Shimamura, Y.; Fujita, M. *J. Org. Chem.* ***1991***, *56*, 2920.

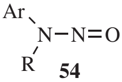
[698]From $NaNO_2$/oxalic acid: Zolfigol, M.A. *Synth. Commun.* ***1999***, *29*, 905. From $NaNO_2$ on wet silica: Zolfigol, M.A.; Ghaemi, E.; Madrikian, E.; Kiany-Burazjani, *M. Synth. Commun.* ***2000***, *30*, 2057.

nitrosamines) are formed.[699] The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-*N*-substituted amides: RCONHR' + HONO $\rightarrow$ RCON(NO)R'.[700] Tertiary amines have also been *N*-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.[701] The group that cleaves appears as an aldehyde or ketone. Other reagents have also been used, for example, NOCl, which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the *N*-nitroso compounds are highly reactive. *N*-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous N_2O_3, N_2O_4,[702] or alkyl nitrites,[703] and, in aqueous or organic solvents, by treatment with $BrCH_2NO_2$.[704] Secondary amines are converted to the *N*-nitroso compound with H_5IO_6 on wet silica.[705]



54

The mechanism of nitrosation is essentially the same as in **13-19** up to the point where **54** is formed. Since this species cannot lose a proton, it is stable and the reaction ends there. The attacking entity can be any of those mentioned in **13-19**. The following has been suggested as the mechanism for the reaction with tertiary amines:[706]

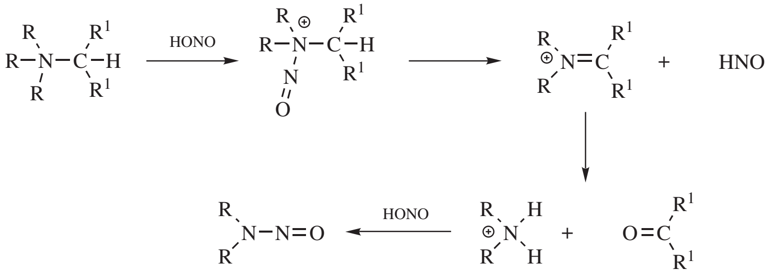
See also, Loeppky, R.N.; Outram, J.R.; Tomasik, W.; Faulconer, J.M. *Tetrahedron Lett.* ***1983***, *24*, 4271.



The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by 2 HNO → $H_2O + N_2O$) and that quinuclidine, where the nitrogen is at a bridgehead, and therefore cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac_2O[707] and with N_2O_4.[708]

Amines and amides can be *N*-nitrated[709] with nitric acid,[710] or NO_2^+,[711] and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.[712] C-Nitrosation is discussed at **11-3** and **12-8**.

OS **I**, 177, 399, 417; **II**, 163, 211, 290, 460, 461, 462, 464 (also see **V**, 842); **III**, 106, 244; **IV**, 718, 780, 943; **V**, 336, 650, 797, 839, 962; **VI**, 542, 981. Also see, OS **III**, 711.

12-51 Conversion of Nitroso Compounds to Azoxy Compounds

In a reaction similar to **13-24**, azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.[713] The position of the oxygen in the final product is determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R' can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds

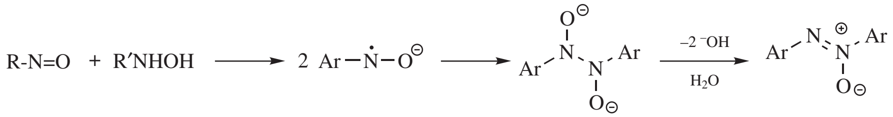
(ArNONAr, ArNONAr′, and Ar′NONAr′) are obtained[714] and the unsymmetrical product (ArNONAr′) is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction (ArNO + Ar′NHOH → Ar′NO + ArNHOH).[715] The mechanism[716] has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:



These radical anions have been detected by esr.[717] This mechanism is consistent with the following result: when nitrosobenzene and phenylhydroxylamine are coupled, ^{18}O and ^{15}N labeling show that the two nitrogens and the two oxygens become equivalent.[718] Unsymmetrical azoxy compounds can be prepared[719] by combination of a nitroso compound with an *N,N*-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents $ArN(MgBr)_2$.[720]

12-52 *N*-Halogenation

N-Halo-de-hydrogenation

$$RNH_2 + NaOCl \longrightarrow RNHCl$$

Treatment with sodium hypochlorite or hypobromite converts primary amines into *N*-halo- or *N,N*-dihaloamines. Secondary amines can be converted to *N*-halo secondary amines. Similar reactions can be carried out on unsubstituted and *N*-substituted amides and on sulfonamides. With unsubstituted amides the *N*-halogen product is seldom isolated but usually rearranges (see **18-13**); however, *N*-halo-*N*-alkyl amides and *N*-halo imides are quite stable. The important reagents NBS and NCS are made in this manner. *N*-Halogenation has also been accomplished with other

sulfur.[736] R can be alkyl or aryl. The same thing can be done with secondary amines, by using $Pd(OAc)_2$–I_2–K_2CO_3.[737] Primary aromatic amines react with β-keto esters and a Mo–ZrO_2 catalyst to give the symmetrical urea.[738] Treatment of a secondary amine with nitrobenzene, selenium, and carbon monoxide leads to the unsymmetrical urea.[739] (*3*) When $PdCl_2$ is the catalyst, primary amines yield isocyanates.[740] Isocyanates can also be obtained by treatment of CO with azides: $RN_3 + CO \rightarrow RNCO$,[741] or with an aromatic nitroso or nitro compound and a rhodium complex catalyst.[742] Primary amines react with di-*tert*-butyltricarbonate to give the isocyanate.[743] Lactams are converted to the corresponding *N*-chloro lactam with $Ca(OCl)_2$ with moist alumina in dichloromethane.[744]

A fourth type of product, a carbamate RNHCOOR', can be obtained from primary or secondary amines, if these are treated with CO, O_2, and an alcohol R'OH in the presence of a catalyst.[745] Primary amines react with dimethyl carbonate in supercritical CO_2 (see p. 414) to give a carbamate.[746] Carbamates can also be obtained from nitroso compounds, by treatment with CO, R'OH, $Pd(OAc)_2$, and $Cu(OAc)_2$,[747] and from nitro compounds.[748] When allylic amines ($R_2C{=}CHRCHRNR'_2$) are treated with CO and a palladium–phosphine catalyst, the CO inserts to produce the β,γ-unsaturated amides ($R_2C{=}CHRCHRCONR'_2$) in good yields.[749] Ring-expanded lactams are obtained from cyclic amines via a similar reaction[750] (see also, **16-22**). Silyloxy carbamates ($RNHCO_2SiR'_3$) can be prepared by the reaction of a primary amine with carbon dioxide and triethylamine, followed by reaction with triisopropylsilyl triflate and tetrabutylammonium fluoride.[751]

Carbon dioxide reacts with amines ($ArNH_2$) and alkyl halides, under electrolysis conditions, to give the corresponding carbamate ($ArNHCO_2Et$).[752] Secondary

CHAPTER 13

Aromatic Substitution, Nucleophilic and Organometallic

On p. 481, it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and it is these exceptions that form the subject of this chapter.[1] Reactions that *are* successful at an aromatic substrate are largely of four kinds: (*1*) reactions activated by electron-withdrawing groups ortho and para to the leaving group; (*2*) reactions catalyzed by very strong bases and proceeding through aryne intermediates; (*3*) reactions initiated by electron donors; and (*4*) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile. It is noted that solvent effects can be important.[2] Also, not all the reactions discussed in this chapter fit into these categories, and certain transition-metal catalyzed coupling reaction are included because they involve replacement of a leaving group on an aromatic ring.

MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.[3] Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.

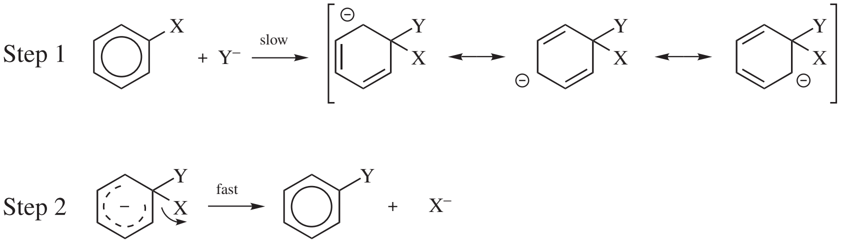
The S_NAr Mechanism[4]

By far the most important mechanism for nucleophilic aromatic substitution consists of two steps, attack of the nucleophilic species at the ipso carbon of the aromatic ring (the carbon bearing the leaving group in this case), followed by elimination of the leaving group and regeneration of the aromatic ring.



1

The first step is usually, but not always, rate determining. It can be seen that this mechanism greatly resembles the tetrahedral mechanism discussed in Chapter 16 and, in another way, the arenium ion mechanism of electrophilic aromatic substitution discussed in Chapter 11. In all three cases, the attacking species forms a bond with the substrate, giving an intermediate, such as **1**, and then the leaving group departs. We refer to this mechanism as the S_NAr mechanism.[5] The IUPAC designation is $A_N + D_N$ (the same as for the tetrahedral mechanism; compare the designation $A_E + D_E$ for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (see p. 864).

There is a great deal of evidence for the mechanism; we shall discuss only some of it.[3] Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between 2,4,6-trinitrophenetole and methoxide ion.[6] Intermediates of this type are stable salts, called *Meisenheimer* or *Meisenheimer–Jackson salts*,[7] and many more have been isolated.[8] The structures

[4]High pressure S_NAr reactions are known. see Barrett, I.C.; Kerr, M.A. *Tetrahedron Lett.* ***1999***, *40*, 2439.
[5]The mechanism has also been called by other names, including the S_N2Ar, the addition–elimination, and the intermediate complex mechanism. See Wu, Z.; Glaser, R. *J. Am. Chem. Soc.* ***2004***, *126*, 10632. See also, Terrier, F.; Mokhtari, M.; Goumont, T.; Hallé, J.-C.; Buncel, E. *Org. Biomol. Chem.* ***2003***, *1*, 1757.
[6]Meisenheimer, J. *Liebigs Ann. Chem.* ***1902***, *323*, 205. Similar salts were isolated even earlier by Jackson, C.L.; see Jackson, C.L.; Gazzolo, F.H. *Am. Chem. J.* ***1900***, *23*, 376; Jackson, C.L.; Earle, R.B. *Am. Chem. J.*, ***1903***, *29*, 89.
[7]Nucleophilic aromatic substitution for heteroatom nucleophiles through electrochemical oxidation of intermediate σ-complexes (Meisenheimer complexes) in simple nitroaromatic compounds has been reported, see Gallardo, I.; Guirado, G.; Marquet, J. *J. Org. Chem.* ***2002***, *67*, 2548.
[8]For a monograph on Meisenheimer salts and on this mechanism, see Buncel, E.; Crampton, M.R.; Strauss, M.J.; Terrier, F. *Electron Deficient Aromatic- and Heteroaromatic-Base Interactions*, Elsevier, NY, ***1984***. For reviews of structural and other studies, see Illuminati, G.; Stegel, F. *Adv. Heterocycl. Chem.* ***1983***, *34*, 305; Artamkina, G. A.; Egorov, M.P.; Beletskaya, I.P. *Chem. Rev.* ***1982***, *82*, 427; Terrier, F. *Chem. Rev.* ***1982***, *82*, 77; Strauss, M.J. *Chem. Rev.* ***1970***, *70*, 667; *Acc. Chem. Res.* ***1974***, *7*, 181; Hall, T.N.; Poranski, Jr., C.F., in Feuer, H. *The Chemistry of the Nitro and Nitroso Groups*, pt. 2; Wiley, NY, ***1970***, pp. 329–384; Crampton, M.R. *Adv. Phys. Org. of several of these intermediates

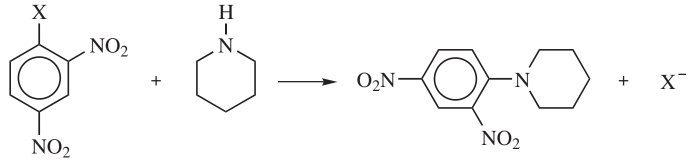
2

have been proved by NMR[9] and by X-ray crystallography.[10] Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the S_N1 or S_N2 mechanisms described in Chapter 10, the Ar–X bond would be broken in the rate-determining step. In the S_NAr mechanism, this bond is not broken until after the rate-determining step (i.e. if step 1 is rate determining). There is some evidence that electron transfer may be operative during this process.[11] We would predict from this that if the S_NAr mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction of dinitro compound **3** with piperidine,



3

when X was Cl, Br, I, SOPh, SO_2Ph, or *p*-nitrophenoxy, the rates differed only by a factor of ~5.[12] This behavior would not be expected in a reaction in which the Ar–X bond is broken in the rate-determining step. We do not expect the rates to be *identical*, because the nature of X affects the rate at which Y attacks. An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the S_N1

[9]First done by Crampton, M.R.; Gold, V. *J. Chem. Soc. B* ***1966***, 893. A good review of spectral studies is found, in Buncel, E.; Crampton, M.R.; Strauss, M.J.; Terrier, F. *Electron Deficient Aromatic- and Heteroaromatic-Base Interactions*, Elsevier, NY, ***1984***, pp. 15–133.

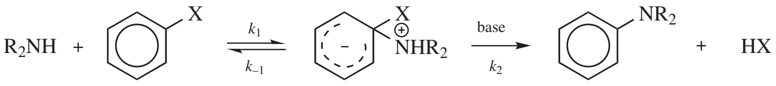
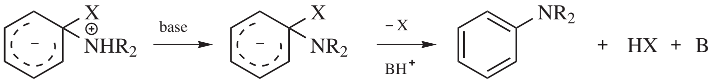
and the S_N2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (p. 475).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. These reactions are catalyzed by bases only when a relatively poor leaving group (e.g., OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.[13] Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily but X does not, so that k_{-1} is large and step 2 is rate determining. This is evidence for the S_NAr mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at



3

low base concentrations: a plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (see p. 660), is also evidence for the S_NAr mechanism. At low base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high base concentration the process is virtually complete: there is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **4** followed by rapid loss of X,



4

and that bases catalyze the reaction by increasing the rate of the deprotonation step.[14] According to the other proposal, loss of X assisted by BH^+ is rate determining.[15] Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents, such as benzene. In both proposals the ordinary S_NAr mechanism

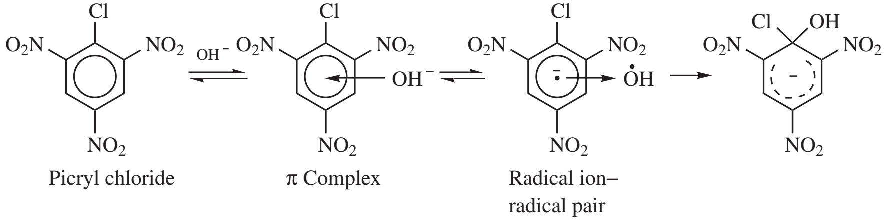
operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism*),[16] while in the other there is a cyclic transition state.[17] Further evidence for the S_NAr mechanism has been obtained from $^{18}O/^{16}O$ and $^{15}N/^{14}N$ isotope effects.[18]

Step 1 of the S_NAr mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and ^{-}OH ions (**13-1**), and spectral evidence has been reported[19] for two intermediates, one a π complex (p. 662), and the other a radical ion–radical pair:



As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (p. 1259) has been demonstrated with an aryl substrate, in certain cases.[20] There is also evidence of an interaction of anions with the π-cloud of aromatic compounds.[21]

The S_N1 Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular S_N1 mechanism (IUPAC: $D_N + A_N$) is very rare; it has only been observed for aryl triflates in which both ortho positions contain bulky groups (*tert*-butyl or SiR_3).[22] It is in reactions with diazonium salts[23] that this mechanism is important:[24]

[16]For a review of this mechanism, see Nudelman, N.S. *J. Phys. Org. Chem.* ***1989***, *2*, 1. See also Nudelman, N.S.; Montserrat, J.M. *J. Chem. Soc. Perkin Trans. 2* ***1990***, 1073.

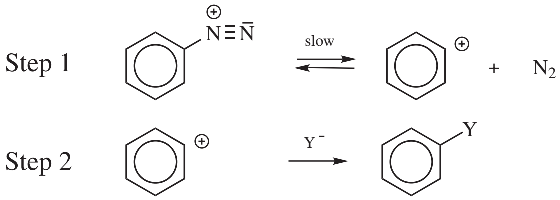
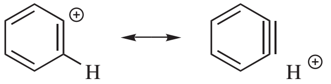
[24]Aryl iodonium salts Ar_2I^+ also undergo substitutions by this mechanism (and by a free-radical mechanism).



Among the evidence for the S_N1 mechanism[25] with aryl cations as intermediates,[26,27] is the following:[28]

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.
2. When high concentrations of halide salts are added, the product is an aryl halide but the rate is independent of the concentration of the added salts.
3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.[29]
4. When reactions were run with substrate deuterated in the ortho position, isotope effects of ~1.22 were obtained.[30] It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation,[31] which is reduced when hydrogen is replaced by deuterium.



5. That the first step is reversible cleavage[32] was demonstrated by the observation that when $\mathrm{Ar}^{15}\overset{\mathrm{H}}{\mathrm{N}}{\equiv}\mathrm{N}$ was the reaction species, recorvered starting

material contained not only $Ar^{15}\overset{H}{N}{\equiv}N$, but also $Ar\overset{H}{N}{\equiv}{}^{15}N$.[33,34] This could arise only If the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating $Ph\overset{H}{N}{\equiv}{}^{15}N$ with unlabeled N_2 at various pressures. At 300 atm, the recovered product had lost ~3% of the labeled nitrogen, indicating that PhN_2^+ was exchanging with atmospheric N_2.[34]

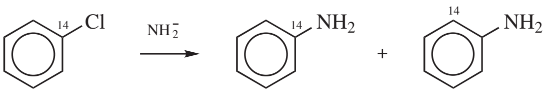
There is kinetic and other evidence[35] that step 1 is more complicated and involves two steps, both reversible:

$$ArN_2^+ \rightleftharpoons \underset{\mathbf{5}}{[Ar^+ \ N_2]} \rightleftharpoons Ar^+ + N_2$$

Intermediate **5**, which is probably some kind of a tight ion–molecule pair, has been trapped with carbon monoxide.[36]

The Benzyne Mechanism[37]

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the S_NAr mechanism (or the S_N1 mechanism). These substitutions occur on aryl halides that have no activating groups; bases are required that are stronger than those normally used; and most interesting of all, the incoming group does not always take the position vacated by the leaving group. That the latter statement is true was elegantly demonstrated by the reaction of 1-^{14}C-chlorobenzene with potassium amide:



The product consisted of almost equal amounts of aniline labeled in the 1 position and in the 2 position.[38]

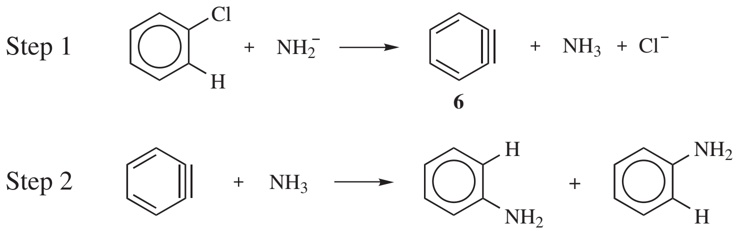
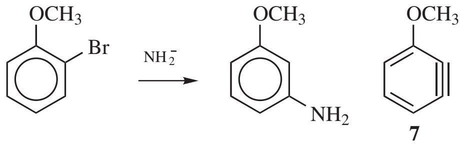
A mechanism that can explain all these facts involves elimination followed by addition. In step 1, a suitable base removes the ortho hydrogen, with subsequent (or concomitant) loss of the chlorine (leaving group) to



6

generate symmetrical intermediate **6**[39] is called benzyne (see below).[40] In step 2, benzyne is attacked by the NH_3 at either of two positions, which explains why about half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position. The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect. Other evidence for this mechanism is the following:

1. If the aryl halide contains two ortho substituents, the reaction should not be able to occur. This is indeed the case.[36]
2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution*[41] and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.[42] In this particular case, only the meta isomer is



7

formed. The reason a 1:1 mixture is not formed is that the intermediate **7** is not symmetrical and the methoxy group directs the incoming group meta, but not ortho (see p. 867). However, not all cine substitutions proceed by this kind of mechanism (see **13-30**).
3. The fact that the order of halide reactivity is Br > I > Cl > F (when the reaction is performed with KNH_2 in liquid NH_3) shows that the S_NAr mechanism is not operating here.[38]

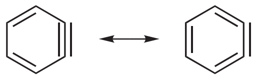
[41]For a review, see Suwiń ski, J.; wierczek, K. *Tetrahedron* ***2001***, *57*, 1639.
[42]This example is from Gilman, H.; Avakian, S. *J. Am. Chem. Soc.* ***1945***, *67*, 349. For a table of many such examples, see Bunnett, J.F.; Zahler, R.E. *Chem. Rev.* ***1951***, *49*, 273, p. 385.

In the conversion of the substrate to **7**, either proton removal or subsequent loss of halide ion can be rate determining. In fact, the unusual leaving-group order just mentioned (Br > I > Cl) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate-determining and the rate order for this step is F > Cl > Br > I. When Cl or F is the leaving group, cleavage of the C–X bond is rate determining and the order for this step is I > Br > Cl > F. Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with $^{-}NH_2$.[43] In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore, a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be I > Br > Cl.[43,44]

Species, such as **6** and **7**, are called *benzynes* (sometimes *dehydrobenzenes*), or more generally, *arynes*,[45] and the mechanism is known as the *benzyne mechanism*. Benzynes are very reactive. Neither benzyne nor any other aryne has yet been isolated under ordinary conditions,[46] but benzyne has been isolated in an argon matrix at 8 K,[47] where its IR spectrum could be observed. In addition, benzynes can be trapped; for example, they undergo the Diels–Alder reaction (see **15-60**). Note that the extra pair of electrons does not affect the



A **B**

aromaticity. However, evaluation by a series of aromaticity indicators, including magnetic susceptibility anisotropies and exaltations, nucleus-independent chemical shifts (NICS), and aromatic stabilization energies, and valence-bond Pauling resonance energies point to the *o*-benzyne > *m*-benzyne > *p*-benzyne aromaticity order.[48] The relative order with respect to benzene depends on the aromaticity criterion.[48] The aromtic sextet from the aromatic precursor functions as a closed ring, and the two additional electrons are merely located in a π orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid. The IR spectrum, mentioned above, indicates that **A** contributes more than **B**. Not only benzene rings, but other aromatic

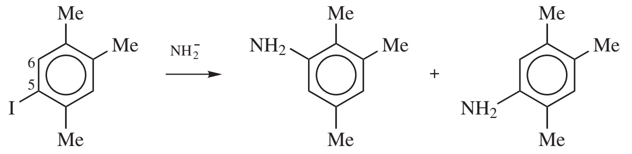
rings[49] and even nonaromatic rings (p. 475) can react through this kind of intermediate. Of course, the non-aromatic rings do have a formal triple bond. When a benzyne unit is fused to a small ring, strain induced regioselectivity observed in its reactions.[50]

The $S_{RN}1$ Mechanism

When 5-iodo-1,2,4-trimethylbenzene **7** was treated with KNH_2 in NH_3, **8** and **10** were formed in the ratio 0.63:1. From what we have already seen, the presence of an unactivated substrate, a strong base, and the occurrence of cine substitution along with normal substitution would be strong indications of a benzyne mechanism. Yet if that were so, the 6-iodo isomer of **8** should have given **9** and **10** in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of **9–10** was 5.9:1 (the chloro and bromo analogs did give the same ratio, 1.46:1, showing that the benzyne mechanism may be taking place there).



8 **9** **10**

To explain the iodo result, it has been proposed[51] that besides the benzyne mechanism, this free-radical mechanism is also operating here:

$$\mathrm{ArI} \xrightarrow[\text{donor}]{\text{electron}} \mathrm{ArI}^{\bullet -} \longrightarrow \mathrm{Ar}^{\bullet} + \mathrm{I}^-$$

$$\mathrm{Ar}^{\bullet} + \mathrm{NH_2^-} \longrightarrow \mathrm{ArNH_2^{\bullet -}} + \mathrm{ArI} \longrightarrow \mathrm{ArNH_2} + \mathrm{ArI}^{\bullet -}$$

followed by terminations steps

This is called the $S_{RN}1$ mechanism,[52] and many other examples are known (see **13-3**, **13-4**, **13-6**, **13-14**). The IUPAC designation is $T + D_N + A_N$.[53] Note that the

[53]The symbol T is used for electron transfer.

last step of the mechanism produces $ArI^{\bullet -}$ radical ions, so the process is a chain mechanism (see p. 936).[54] An electron donor is required to initiate the reaction. In the case above it was solvated electrons from KNH_2 in NH_3. Evidence was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the cine substitution. Further evidence for the $S_{RN}1$ mechanism was that addition of radical scavengers (which would suppress a free-radical mechanism) led to **9:10** ratios much closer to 1.46:1. Numerous other observations of $S_{RN}1$ mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.[55] Further evidence for the $S_{RN}1$ mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by $Ar^{\bullet}$ of H from the solvent NH_3. Besides initiation by solvated electrons,[56] $S_{RN}1$ reactions have been initiated photochemically,[57] electrochemically,[58] and even thermally.[59]

The $S_{RN}1$ reactions have a fairly wide scope. The efficiency of the reaction has been traced to the energy level of the radical anion of the substitution product.[60] There is no requirement for activating groups or strong bases, but in DMSO haloarenes are less reactive as the stability of the anion increases.[61] The reaction has also been done in liquid ammonia, promoted by ultrasound (p. 349),[62] and ferrous ion has been used as a catalyst.[63] Alkyl, alkoxy, aryl, and COO^- groups do not interfere, although Me_2N, O^-, and NO_2 groups do interfere. Cine substitution is not found.

Other Mechanisms

There is no clear-cut proof that a one-step S_N2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic S_N2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* S_NAr mechanism. A "clean" example of a $S_{RN}2$ reaction has been reported, the conversion of **11** to **12** in methanol.[64] Both the $S_{RN}1$ and $S_{RN}2$ reactions have been reviewed.[65]

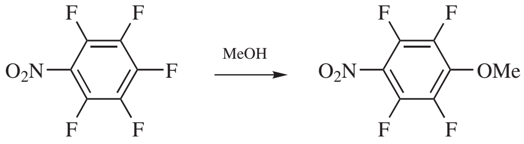
Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see **13-17**). A new mechanism has been reported in aromatic chemistry, a reductively activated 'polar' nucleophilic aromatic substitution.[66] The reaction of phenoxide with *p*-dinitrobenzene in DMF shows radical features that cannot be attributed to a radical anion, and it is not $S_{RN}2$. The new designation was proposed to account for these results.



11 **12**

REACTIVITY

The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11) equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogens that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

S_NAr Mechanism. These substitutions are accelerated by electron-withdrawing groups, especially in positions ortho and para to the leaving group[67] and hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Chapter 11 (p. 660). Table 13.1 contains a list of groups arranged approximately in order of activating or deactivating ability.[68] Nitrogen atoms are also strongly activating (especially to the α and γ positions) and are even more so when quaternized.[69] Both 2- and 4-chloropyridine, for example, are often used as substrates. Heteroaromatic amine *N*-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.[70]

[66]Marquet, J.; Casado, F.; Cervera, M.; Espín, M.; Gallardo, I.; Mir, M.; Niat, M. *Pure Appl. Chem.* ***1995***, *67*, 703.

[67]The effect of meta substituents has been studied much less, but it has been reported that here too, electron-withdrawing groups increase the rate: See Nurgatin, V.V.; Sharnin, G.P.; Ginzburg, B.M. *J. Org. Chem, USSR* ***1983***, *19*, 343.

[a]For reaction (*a*) the rates are relative to **H**; *for (b)* they are relative to NH_2.
[b]The comments on the left column are from Ref. 73.

The most highly activating group, N_2^+, is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound, such as *p*-nitroaniline or *p*-chloroaniline, the group para to the diazonium group is replaced by OH from the solvent or by X from $ArN_2^+\ X^-$, to the surprise and chagrin of the investigator, who was trying only to replace the diazonium group and to leave the para group untouched. By far, the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).[74] Polyfluorobenzenes[75] (e.g., C_6F_6), also undergo aromatic nucleophilic substitution quite well.[76] Benzene rings that lack activating substituents are generally not useful substrates for the S_NAr mechanism, because the two extra electrons in **1** are in an antibonding orbital (p. 34). Activating groups, by withdrawing electron density, are able to stabilize the intermediates and the

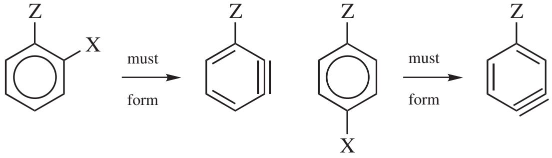
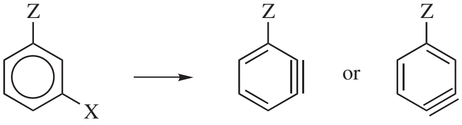
transition states leading to them. Reactions taking place by the S_NAr mechanism are also accelerated when the aromatic ring is coordinated with a transition metal.[77]

Just as electrophilic aromatic substitutions were found more or less to follow the Hammett relationship (with σ^+ instead of σ; see p. 402), so do nucleophilic substitutions, with σ^- instead of σ for electron-withdrawing groups.[78]

Benzyne Mechanism. Two factors affect the position of the incoming group, the first being the direction in which the aryne forms.[79] When there are groups ortho or para to the leaving group, there is no choice:



but when a meta group is present, the aryne can form in two different ways:



In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the ortho hydrogen while an electron-donating Z favors removal of the para hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate, and this in turn also depends on the field effect of Z. For *-I* groups, the more stable carbanion is the one in which the negative charge is closer to the substituent. These principles are illustrated by the reaction of the three dichlorobenzenes (**13-15**) with alkali-metal

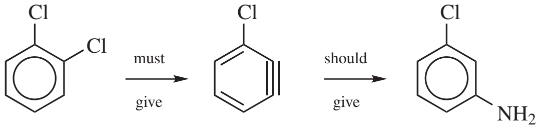
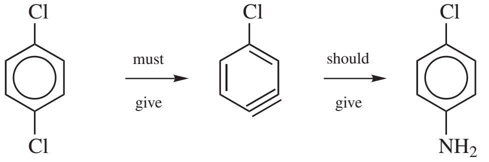
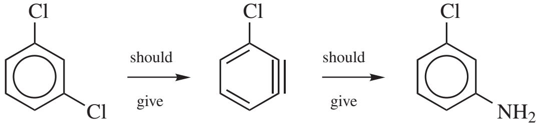
amides to give the predicted products shown.



13



14



15

In each case, the predicted product was the one chiefly formed.[80] The observation that *m*-aminoanisole is obtained, mentioned on p. 860, is also in accord with these predictions.

The Effect of the Leaving Group[81]

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate, NR_3^+, etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups NO_2, OR, OAr, SO_2R,[82] and SR, which are not generally lost in aliphatic systems, *are* leaving groups when attached to aromatic rings. Surprisingly, NO_2 is a particularly good leaving group.[83] An approximate order of leaving-group ability is[84] $F > NO_2 > OTs > SOPh > Cl,\ Br,\ I > N_3 > NR_3^+ >$ OAr, OR, SR, NH_2. However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that $C_6Cl_5OCH_3$ treated with NH_2^- gives mostly $C_6Cl_5NH_2$; that is, one methoxy group is replaced in preference to five chlorines.[85] As usual, OH can be a leaving group if it is converted to an inorganic ester. Among

the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually Cl > Br > I, but not always.[86] The leaving-group order is quite different from that for the S_N1 or S_N2 mechanisms. The most likely explanation is that the first step of the S_NAr mechanism is usually rate determining, and this step is promoted by groups with strong *–I* effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the S_NAr mechanism is rate determining or when the benzyne mechanism is operating. The four halogens, as well as SPh, NMe_3^+, and $OPO(OEt)_2$, have been shown to be leaving groups in the $S_{RN}1$ mechanism.[55] The only important leaving group in the S_N1 mechanism is N_2^+.

The Effect of the Attacking Nucleophile[87]

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is $^-NH_2 > Ph_3C^- > PhNH^-$ (aryne mechanism) > $ArS^- > RO^{\neq} > R_2NH > ArO^- > {}^-OH > ArNH_2 > NH_3 > I^- > Br^- > Cl^- > H_2O > ROH$.[88] As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions, for example, ^-OH, a stronger base than ArO^-, is a poorer nucleophile.[89] In a series of similar nucleophiles, such as substituted anilines, nucleophilicity *is* correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts and in the von Richter (**13-30**) and Rosenmund-von Braun (**13-8**) reactions, which are special cases.

REACTIONS

In the first part of this section, reactions are classified according to attacking species, with all leaving groups considered together, except for hydrogen and N_2^+, which are treated subsequently. Finally, a few rearrangement reactions are discussed.

ALL LEAVING GROUPS EXCEPT HYDROGEN AND N_2^+

A. Oxygen Nucleophiles

13-1 Hydroxylation of Aromatic Compounds

Hydroxy-de-halogenation

$$\text{ArBr} + \text{OH}^- \longrightarrow \text{ArOH}$$

Aryl halides are converted to phenols if activating groups are present or if exceedingly strenuous conditions are employed.[90] When the reaction is carried out at high temperatures, cine substitution is observed, indicating a benzyne mechanism.[91] The reaction has been done using NaOH on Montmorillonite K10 and $AgNO_3$ with microwave irradiation.[92]

A slightly related reaction involves the amino group of naphthylamines can be replaced by a hydroxyl group by treatment with aqueous bisulfite.[93] The scope is greatly limited; the amino group (which may be NH_2 or NHR) must be on a naphthalene ring, with very few exceptions. The reaction is reversible (see **13-6**), and both the forward and reverse reactions are called the *Bucherer reaction*.

$$\text{ArMgX} \xrightarrow{\text{B(OMe)}_3} \text{ArB(OMe)}_2 \xrightarrow[\text{H}_2\text{O}_2]{\text{H}^+} \text{ArOH}$$

An indirect method for conversion of an aryl halide to a phenol involves initial conversion to an organometallic, followed by oxidation to the phenol. For the conversion of aryl Grignard reagents to phenols, a good procedure is the use of trimethyl borate followed by oxidation with H_2O_2 in acetic acid[94] (see **12-31**). Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal such as lithium, followed by oxidation with alkaline H_2O_2.[95] Arylboronic acids, $ArB(OH)_2$, are oxidized by aqueous hydrogen peroxide to give the corresponding phenol.[96] The reaction of an aromatic compound with a borane in the

presence of an iridium catalyst, followed by oxidation with aqueous Oxone® gave the corresponding phenol.[97] Aryllithium reagents have been converted to phenols by treatment with oxygen.[98] In a related indirect method, arylthallium bis(trifluoroacetates) (prepared by **12-23**) can be converted to phenols by treatment with lead tetraacetate followed by triphenylphosphine and then dilute NaOH.[99] Diarylthallium trifluoroacetates undergo the same reaction.[100]

OS **I**, 455; **II**, 451; **V**, 632. Also see, OS **V**, 918.

13-2 Alkali Fusion of Sulfonate Salts

Oxido-de-sulfonato-substitution

$$ArSO_3^- \xrightarrow[300\text{–}320^\circ C]{\text{NaOH fusion}} ArO^-$$

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is obscure, but a benzyne intermediate has been ruled out by the finding that cine substitution does not occur.[101]

OS **I**, 175; **III**, 288.

13-3 Replacement by OR or OAr

Alkoxy-de-halogenation

$$ArBr + OR^- \longrightarrow ArOR$$

This reaction is similar to **13-1** and, like that one, generally requires activated substrates.[90,102] With unactivated substrates, side reactions predominate, though aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO^- in HMPA.[103] This reaction gives better yields than **13-1** and is

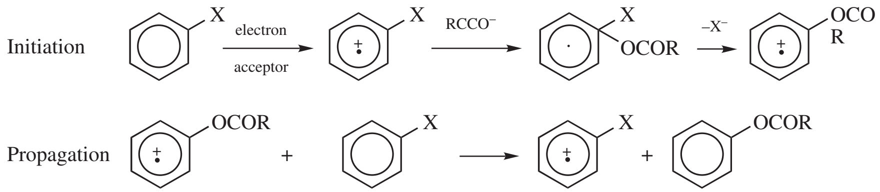
used more often. A good solvent is liquid ammonia. Aryl chlorides react with phenol and KOH with microwave irradiation to give the diaryl ether.[104] Potassium phenoxide reacts with iodobenzene in an ionic solvent at 100°C with CuCl.[105] The NaOMe reacted with *o*- and *p*-fluoronitrobenzenes ~10^9 times faster in NH_3 at −70°C than in MeOH.[106] Phase-transfer catalysis has also been used.[107] Phenols reacted with aryl fluorides with K_2CO_3/DMSO[108] or aryl chlorides with KOH,[109] with microwave irradiation, to give the diaryl ether. Aryl carbonates react with aryl oxides.[110] Phenolic compounds react with aryl fluorides in the presence of LiOH in DMF to give the diaryl ether.[111] Aryl iodides react with phenols in the presence of K_2CO_3, CuI and Raney nickel alloy.[112]

In addition to halides, leaving groups can be other OR, and so on, even OH.[113] Acid salts, $RCOO^-$, are sometimes used as nucleophiles. Good yields of aryl benzoates can be obtained by the treatment of aryl halides with cuprous benzoate in diglyme or xylene at 140–160°C.[114] Unactivated substrates have been converted to carboxylic esters in low-to-moderate yields under oxidizing conditions.[115] The following chain mechanism, called the $S_{ON}2$ mechanism,[116] has been suggested:[115]



For aroxide nucleophiles, the reaction is promoted by copper salts,[117] and when these are used, activating groups need not be present. Indeed, unactivated aryl

halides, such as 4-iodoanisole, were coupled to allylic alcohols using a CuI catalyst in the presence of 2% 1,10-phenanthroline and cesium carbonate.[118] This method of preparation of diaryl ethers is called the *Ullmann ether synthesis*[119] and should not be confused with the Ullmann biaryl synthesis (**13-11**). The reactivity order is typical of nucleophilic substitutions, despite the presence of the copper salts.[120] Because aryloxycopper(I) reagents ArOCu react with aryl halides to give ethers, it has been suggested that they are intermediates in the Ullmann ether synthesis.[121] Indeed, high yields of ethers can be obtained by reaction of ROCu or ArOCu with aryl halides.[122] Alcohols, via the alkoxide, displace the halogen group in aryl halides to give aryl ethers in the presence of a palladium catalyst.[123] A palladium catalyzed, intramolecular displacement of an aryl halide with a pendant alkoxide unit leads to dihydrobenzofurans.[124] Nickel catalysts have also been used.[125] The reaction has been done by heating aryl iodides and phenols in an ionic liquid.[126]

Unactivated substrates also react with phenoxide ion with electrochemical catalysis in liquid NH_3–Me_2SO, to give diaryl ethers, presumably by the $S_{RN}1$ mechanism.[127] Diaryl ethers can be prepared from activated aryl halides by treatment with a triaryl phosphate, $(ArO)_3PO$.[128]

Aryl thiols and thioethers can be prepared by reactions that are similar to **13-1** and **13-3**.[129] Activated aryl halides generally give good results, but side reactions are occasionally important. Some reagents give the thiol directly. 4-bromonitrobenzene reacts with Na_3SPO_3, in refluxing methanol, to give 4-nitrothiophenol.[130] Diaryl sulfides can be prepared by the use of $^-$SAr.[131] Even unactivated aryl halides react with $^-$SAr if polar aprotic solvents, for example, DMF,[132] DMSO[133] 1-methyl-2-pyrrolidinone,[134] or HMPA,[135] are used, though the mechanisms are still mostly or entirely nucleophilic substitution. 2-Iodothiophene reacts directly with thiophenol to give 2-phenylthiothiophene.[136] Unactivated aryl halides also give good yields of sulfides on treatment with ArS^- or RS^- (generated *in situ* from the corresponding thiol) in the presence of a palladium catalyst.[137] Copper catalysts have also been used.[138] Thiophenols were coupled to indoles in the presence of a vanadium catalyst.[139] Aryl iodides react with dialkyl disulfides and a nickel catalyst to give aryl alkyl sulfides.[140] Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS^- in liquid ammonia under irradiation.[141] The mechanism in this case is probably $S_{RN}1$. The reaction (with unactivated halides) has also been carried out electrolytically, with a nickel complex catalyst.[142]

Arylboronic acids, $(ArB(OH)_2$, react with thiols and copper(II) acetate to give the corresponding alkyl aryl sulfide.[143] Arylboronic acids also react with *N*-methylthiosuccinimide, with a copper catalyst, to give the aryl methyl sulfide.[144] In the presence of a palladium catalyst, thiophenols react with diaryliodonium salts, Ar_2I^{+-} BF_4, to give the unsymmetrical diaryl sulfide.[145]

Other sulfur nucleophiles also react with activated aryl halides:

$$2\,ArX + S_2^{2-} \longrightarrow Ar{-}S{-}S{-}Ar \qquad ArX + SCN^- \longrightarrow ArSCN$$
$$ArX + SO_3^{2-} \longrightarrow Ar{-}SO_3^- \qquad ArX + RSO_2^- \longrightarrow Ar{-}SO_2{-}R$$

Aryl sulfones have been prepared from sulfinic acid salts, aryl iodides and CuI.[146] Formation of thiocyanates from unactivated aryl halides has been accomplished with charcoal supported copper(I) thiocyanate.[147] The copper catalyzed reaction of NaO_2SMe and aryl iodides give the aryl methyl sulfone.[148] A similar synthesis of diaryl sulfones has been reported using a palladium catalyst.[149]

An indirect method for the synthesis of aryl alkyl sulfides involves treatment of an aryl halide with butyllithium and then elemental sulfur. The resulting thiophenoxide anion reacts with an alkyl halide to give the targeted sulfide.[150]

Aryl selenides (ArSeAr and ArSeAr') can be prepared by similar methodology. Symmetrical diaryl selenides were prepared by the reaction of iodobenzene with diphenyl diselenide (PhSeSePh), in the presence of Mg and a copper catalyst.[151] Aryl halides react with tin selenides ($ArSeSnR_3$), with a copper catalyst, to give the diaryl selenide.[152]

Activated aryl halides react quite well with ammonia and with primary and secondary amines to give the corresponding arylamines. Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Picryl chloride (2,4,6-trinitrochlorobenzene) is often used to form amine derivatives. 2,4-Dinitrofluorobenzene is used to tag the amino end of a peptide or protein chain. Other leaving groups in this reaction may be NO_2,[153] N_3, OSO_2R, OR, SR, N=NAr (where Ar contains electron-withdrawing groups)[154] and even NR_2.[155]

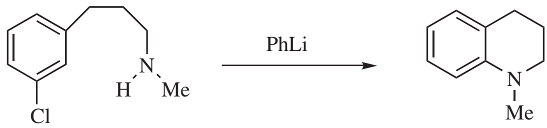
Aryl triflates were shown to react directly with secondary amines in *N*-methylpyrrolidine solvent using microwave irradiation.[156] Activated halides can be converted to diethylamino compounds ArX → $ArNMe_2$ by treatment with HMPA.[157] Aniline derivatives react with activated aromatic rings, in the presence of tetrabutylammonium fluoride and under photolysis conditions, to give a *N,N*-diarylamine.[158] Arylation of amines with aryl halides has also been done in ionic liquids.[159]

Unactivated aryl halides can be converted to amines by the use of $NaNH_2$, NaNHR, or $NaNR_2$.[160] Lithium dialkylamides also react with aryl halides to give the *N*-arylamine.[161] With these reagents, the benzyne mechanism generally operates, so cine substitution is often found. The reaction of an amine, an aryl halide, and potassium *tert*-butoxide generates the *N*-aryl amine.[162] *N*-Arylation was accomplished with butyllithium and a secondary amine using Ni/C-diphenylphosphinoferrocene (dppf).[163] Ring closure has been effected by this type of reaction,[164] as in the conversion of **16** to the tetrahydroquinoline.



16

Larger rings can be prepared using this approach: 8 and even 12 membered. Triarylamines have been prepared in a similar manner from ArI and Ar_2' NLi, even with unactivated ArI.[165] In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K_2CO_3 and CuI to give an *N*-acetyldiarylamine, which can be hydrolyzed to a diarylamine: ArBr + Ar′NHAc → ArAr′NAc.[166] Aryl fluorides react in the presence of KF-alumina and 18-crown-6 in DMSO.[167] Lithium amides have been shown to react directly with aryl halides.[168] Aryl fluorides react

with amines in the presence of potassium carbonate/DMSO and ultrasound,[169] and aryl chlorides react on basic alumina with microwave irradiation.[170] 2-Chloronitrobenzene also reacts with aniline derivatives directly with microwave irradiation.[171] 2-Fluoropyridine reacts with R_2NBH_3Li to give the 2-aminoalkylpyridine.[172]

The reaction of amines with unactivated aryl halides requires a catalyst in most cases to initiate the reaction. There are several approaches that result in *N*-aryl amines, but recent work with aryl halides, amines, and palladium catalysts has proven quite useful.[173] Aryl halides react with amines (including aniline derivatives) in the presence of palladium catalysts to give the *N*-aryl amine.[174] Palladium catalysts have been used with aniline and or triflates[175] to give the secondary amine. Palladium catalysts have been used in conjunction with aryl halides and aliphatic amines–amide bases.[176] A considerable amount of work[177] has been done to vary the nature of the ligand and the palladium catalyst, as well as the base.[178] Aryl halides also react with aliphatic amines,[179] including cyclopropylamines,[180] and an intramolecular version of this reaction generates bicyclic amines (hydroindole derivatives).[181] Primary aliphatic amines can be converted to tertiary *N,N*-diarylalkylamines in a two-step procedure using palladium catalysts.[182] Aryl halides are

converted to *N,N*-diaryl tertiary amines by reaction with *N*-alkylaniline derivatives and a palladium catalyst.[183] Beginning with a primary aromatic amine and two different aryl halides (ArBr and Ar'Cl), a triarylamine with three different aryl groups can be prepared using a palladium catalyst.[184] Polymer-bound phosphine ligands have been used in conjunction with a palladium catalyst,[185] and polymer-bound amines have been *N*-arylated with a palladium catalyst followed by treatment with trifluoroacetic acid to release the aniline derivative.[186] Palladium-catalyzed aminoalkylation of aryl halides has been reported using microwave irradiation.[187] Aryl halides (Ar–X) have also been converted to the aniline derivative (Ar–NH_2) by reaction of the halide with an imine and a palladium catalyst, followed by hydrolysis.[188] Similarly, aniline derivatives have been prepared by the reaction of aryl chlorides with silylamines (Ph_3SiNH_2) using lithium hexamethyldisilazide and a palladium catalyst.[189] Amines react with $Ph_2I^+BF_4^-$, in the presence of palladium catalysts,[190] or a CuI catalyst[191] to give the *N*-phenyl amine. These reactions have been done in ionic liquids using a palladium catalyst.[192] Arylation of the amine unit of primary enamino ketones was accomplished using a palladium catalyst.[193] Mono-arylation of a 1,2-diamine is possible.[194] Aminoalkylation of heteroaromatic rings is possible, as in the reaction of 3-bromothiophene with a primary amine and a palladium catalyst.[195] 2-Halopyridines react to give the 2-aminoalkyl pyridine.[196] Carbazole derivatives were prepared from 2-iodoaniline and 2-trimethylsilylphenol *O*-triflates, using cesium fluoride and then a palladium catalyst.[197]

Nickel catalysts have been used in the reaction of aryl halides with *N*-alkyl aniline derivatives.[198] Nickel catalyst also allow the conversion of aryl halides to *N*-arylamines via reaction with aliphatic amines.[199] An intramolecular reaction of a

pendant aminoalkyl unit with an aryl chloride moiety, catalyzed by nickel(0) gave a dihydroindole.[200] Copper catalysts allow the reaction of diarylamines and aryl halides to give the corresponding triarylamine,[201] or with aliphatic amines to give the *N*-arylamine.[202] Aniline reacts with aryl iodides an a copper catalyst and potassium *tert*-butoxide to give triphenylamine.[203] A polymer-bound copper catalyst was used in conjunction with aliphatic amines and arylboronic acids.[204] Amino alcohols react with aryl iodides and a copper catalyst to give the *N*-arylamino alcohol.[205] Treatment of alkylamines with arylboronic acids $ArB(OH)_2$ and $Cu(OAc)_2$ gave the *N*-aryl amine in 63% yield.[206] Similar reaction with arylamines, such as aniline, gave the diarylamine.[207] Arylboronic acids convert aziridines to *N*-arylaziridines,[208] and amino esters to *N*-arylated amino esters,[209] both reactions using a copper catalyst. An arylbismuth reagent reacts with aliphatic amines, in the presence of copper(II) acetate, to give an *N*-arylamine.[210] *N*-Arylation of pyrroles was accomplished by the reaction of an arylboronic acid and a copper catalyst.[211] *N*-Arylindoles[212] and *N*-arylimidazoles[213] were prepared from aryl halide using a copper catalyst. Diarylzinc reagents react with *N*-(OBz) amine derivatives, with a copper catalyst, to give the *N*-aryl amine.[214]

In a related reaction, trifluoroarylboronates react with copper(II) acetate and then an aliphatic amine to give the *N*-phenylamine.[215]

The metal catalyzed reaction with ammonia or amines likely proceeds by the S_NAr mechanism.[216] This reaction, with phase-transfer catalysis, has been used to synthesize triarylamines.[217] Copper ion catalysts (especially cuprous oxide or iodide) also permit the Gabriel synthesis (**10-41**) to be applied to aromatic substrates. Aryl bromides or iodides are refluxed with potassium phthalimide and

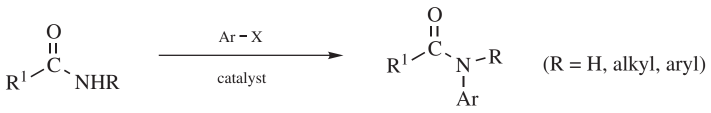
Cu_2O or CuI in dimethylacetamide to give *N*-aryl phthalimides, which can be hydrolyzed to primary aryl amines.[218]

In certain cases, the $S_{RN}1$ mechanism has been found (p. 550). When the substrate is a heterocyclic aromatic nitrogen compound, still a different mechanism [the S_N(ANRORC) mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.[219]

There are a number of indirect approaches for the preparation of aryl amines. Activated aromatic compounds can be directly converted to the *N*-aryl amine with hydroxylamine in the presence of strong bases.[220] Conditions are mild and yields are high. Aryl halides can be converted to the corresponding Grignard reagent (**12-38**). Subsequent reaction of arylmagnesium halides with allyl azide ($CH_2{=}CHCH_2N_3$) followed by hydrolysis leads to the corresponding aniline derivative.[221] Aryl halides can be converted to the aryllithium via halogen–lithium exchange or hydrogen–lithium exchange (**12-38**, **12-39**). Molecular nitrogen (N_2) reacts with aryllithium compounds in the presence of compounds of such transition metals as titanium (e.g., $TiCl_4$), chromium, molybdenum, or vanadium to give (after hydrolysis) primary aromatic amines ($ArLi + N_2 +$ transition metal salts $\rightarrow ArNH_2$, after hydrolysis).[222] Primary aromatic amines $ArNH_2$ were converted to diaryl amines ArNHPh by treatment with $Ph_3Bi(OAc)_2$[223] and a copper powder catalyst.[224] Aryl Grignard reagents react with nitroaryl compounds to give, after reduction with $FeCl_3/NaBH_4$, a diaryl amine.[225]



The use of transition-metal catalysts allows aryl halides to react with the nitrogen of amides or carbamates, as well as amines, to give the corresponding *N*-aryl amide or *N*-aryl carbamate. Amides react with aryl halides in the presence of a palladium catalyst[226] or a copper catalyst.[227] *N*-Aryl lactams are prepared by the reaction of a lactam with an aryl halide in the presence of a palladium catalyst.[228]

β-Lactams also react.[229] The reaction of 2-oxazolidinones with aryl halides in the presence of a palladium catalyst gave the *N*-aryl-2-oxazolidinone.[230] Amides react with $PhSi(OMe)_3/Cu(OAc)_2/Bu_4NF$ to give the *N*-aryl amide.[231] *N*-Boc hydrazine derivatives ($BocNHNH_2$) gave the *N*-phenyl derivative $BocN(Ph)NH_2$ when reacted with iodobenzene and a catalytic amount of CuI and 10% of 1,10-phenanthroline.[232] 3-Bromothiophene was converted to the 3-amido derivative with an amide and CuI-dimethylethylenediamine,[233] and *N*-(2-thiophene)-2-pyrrolidinone was similarly prepared from 2-iodothiophene, the lactam and a copper catalyst.[234] *N*-Arylation of urea is also possible using a copper catalyst.[235] The reaction of a vinyl triflate with benzamide and a palladium catalyst gave the corresponding enamide (C=C–NHC=O).[236]

The transition-metal catalyzed couplings of primary or secondary phosphines with aryl halides or sulfonate esters to give arylphosphines is known.[237] Palladium catalyzed conversion of aryl halides to aryl phosphines using (trimethylsilyl)diphenylphosphine is known, and tolerates many functional groups (not those that are easily reducible, such as aldehydes because zinc metal[238] is often used as a coreagent), but it is mainly limited to aryl iodides.[239] Diphenylphosphine reacts with aryl iodides and a copper catalyst to give the triarylphosphine.[240] Aryl iodides also react with secondary phosphine and 5% Pd/C to give the *P*-arylphosphine.[241] Tertiary phosphines can also be used via aryl–aryl exchange, as in the reaction of an aryl triflate and triphenylphosphine and a palladium catalyst, for example, gave the arylphosphine ($ArPPh_2$).[242]

Arylsulfonic acid chlorides ($ArSO_2Cl$) have been shown to react with arylboronic acids, $Ar'B(OH)_2$, in the presence of a palladium catalyst, to give the corresponding biaryl (Ar–Ar').[243]

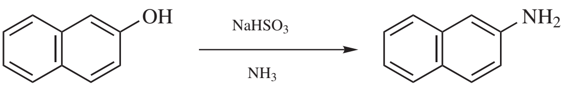
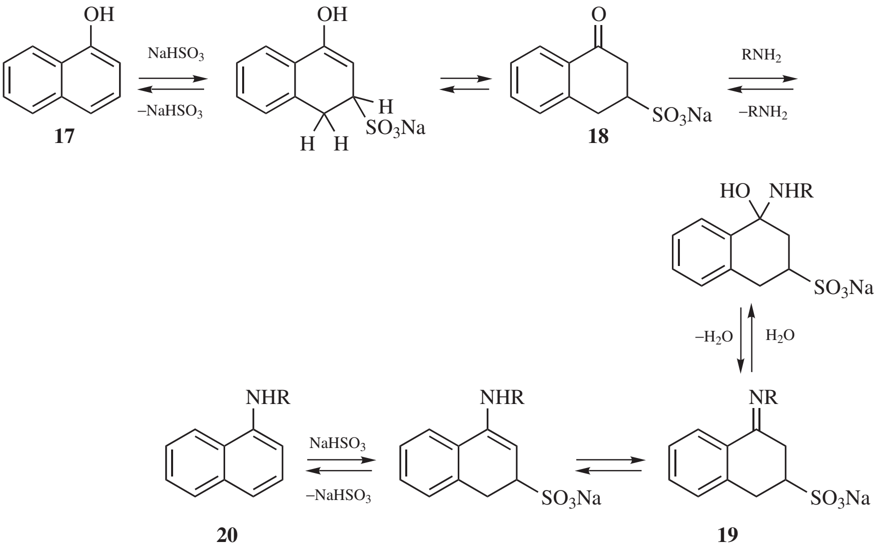
13-6 Replacement of a Hydroxy Group by an Amino Group

Amino-de-hydroxylation



The reaction of naphthols with ammonia and sodium bisulfite[81] is called the *Bucherer reaction*. Primary amines can be used instead of ammonia, in which case *N*-substituted naphthylamines are obtained. In addition, primary naphthylamines can be converted to secondary ($ArNH_2 + RNH_2 + NaSO_3 \rightarrow ArNHR$), by a transamination reaction. The mechanism of the Bucherer reaction amounts to a kind of overall addition–elimination, via **18** and **19**.[244]



The first step in either direction consists of addition of $NaHSO_3$ to one of the double bonds of the ring, which gives an enol from **17** (or enamine from **20**) that tautomerizes to the keto form **18** (or imine form, **19**). The conversion of **18** to **19** (or vice versa) is an example of **16-13** (or **16-2**). Evidence for this mechanism was the isolation of **18**[245] and the demonstration that for β-naphthol treated with ammonia and HSO_3^-, the rate of the reaction depends only on the substrate and on

[244]Rieche, A.; Seeboth, H. *Liebigs Ann. Chem.* ***1960***, *638*, 66.

[245]Rieche, A.; Seeboth, H. *Liebigs Ann. Chem.* ***1960***, *638*, 43, 57.

HSO_3^-, indicating that ammonia is not involved in the rate-determining step.[246] If the starting compound is a β-naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks meta to the OH or NH_2.[247]

Hydroxy groups on benzene rings can be replaced by NH_2 groups if they are first converted to aryl diethyl phosphates. Treatment of these with KNH_2 and potassium metal in liquid ammonia gives the corresponding primary aromatic amines.[248] The mechanism of the second step is $S_{RN}1$.[249]

OS **III**, 78.

D. Halogen Nucleophiles

13-7 The Introduction of Halogens

Halo-de-halogenation, and so on.

$$Ar{-}X + X'^- \rightleftharpoons Ar{-}X' + X^-$$

It is possible to replace a halogen on a ring by another halogen[250] if the ring is activated. In such cases there is an equilibrium, but it is usually possible to shift this in the desired direction by the use of an excess of added halide ion.[251] A phenolic hydroxy group can be replaced by chloro with PCl_5 or $POCl_3$, but only if activated. Unactivated phenols give phosphates when treated with $POCl_3$: 3 ArOH + $POCl_3$ → $(ArO)_3PO$. Phenols, even unactivated ones, can be converted to aryl bromides by treatment with Ph_3PBr_2[252] (see **10-47**) and to aryl chlorides by treatment with $PhPCl_4$.[253]

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF, DMSO, or dimethyl sulfone.[254] Reaction of aryl halides with Bu_4PF/HF is also effective for exchanging a halogen with fluorine.[255] Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is $I > Br > Cl \gg F$ (which means that iodides cannot normally be made by this method), the S_NAr mechanism is

probably not operating.[256] However, aryl iodides have been prepared from bromides, by the use of Cu supported on charcoal or Al_2O_3,[257] with an excess of NaI and a copper catalyst,[258] and by treatment with excess KI and a nickel catalyst.[259] Interestingly, aryl chlorides have been prepared from aryl iodides using 2 equivalents of $NiCl_2$ in DMF, with microwave irradiation.[260]

An indirect halogen exchange treated aryl bromides with *n*-butyllithium and the 5-(iodomethyl)-γ-butyrolactone, giving the aryl iodide and the lithium salt of 4-pentenoic acid.[261] Aryl iodides[262] and fluorides can be prepared from arylthallium bis(trifluoroacetates) (see **12-23**), indirectly achieving the conversions ArH → ArI and ArH → ArF. The bis(trifluoroacetates) react with KI to give ArI in high yields.[263] Aryllead triacetates $ArPb(OAc)_3$ can be converted to aryl fluorides by treatment with BF_3–etherate.[264] Treatment of $PhB(OH)_2$ with *N*-iodosuccinimide gives iodobenzene.[265] Arylboronic acids (**12-28**) can be converted to the corresponding aryl bromides by reaction with 1,3-dibromo-5,5-dimethylhydantoin and 5 mol % NaOMe.[266] Other aryl halides can be prepared using 1,3-dihalo-5,5-dimethylhydantoins.

OS **III**, 194, 272, 475; **V**, 142, 478; **VIII**, 57; **81**, 98.

The reduction of phenols and phenolic esters and ethers is discussed in Chapter 19 (see **19-38** and **19-35**). The reaction ArX → ArH is treated in Chapter 11 (reaction **11-39**), although, depending on reagent and conditions, it can be nucleophilic or free-radical substitution, as well as electrophilic.

E. Carbon Nucleophiles[267]

Some formations of new aryl–carbon bonds formed from aryl substrates have been considered in Chapter 10 (see **10-57**, **10-68**, **10-76**, **10-77**).

13-8 Cyanation of Aromatic Rings

Cyano-de-halogenation
Cyano-de-metalation

$$\text{Ar-X} \longrightarrow \text{Ar-CN}$$

The reaction between aryl halides and cuprous cyanide is called the *Rosenmund-von Braun reaction*.[268] Reactivity is in the order I > Br > Cl > F, indicating that the S_NAr mechanism does not apply.[269] Other cyanides (e.g., KCN and NaCN) do not react with aryl halides, even activated ones. This reaction has been done in ionic liquids using CuCN.[270] The reaction has also been done in water using CuCN, a phase transfer catalyst, and microwave irradiation.[271]

Aryl halides reaction with metal cyanides, often with another transition metal catalyst, to give aryl nitriles (aryl cyanides). Aryl halides react with $Zn(CN)_2$ and a palladium catalyst, for example, to give the aryl nitrile.[272] Similarly, aryl iodides react with CuCN and a palladium catalyst to give the aryl nitrile.[273] Potassium cyanide (KCN) reacts in a similar manner with a palladium catalyst.[274] Sodium cyanide has been used with a copper catalyst and 20% KI.[275] The reaction of aryl iodides and sodium cyanoborohydride/catechol, with a palladium catalyst, generates the aryl nitrile.[276] Aryl bromides react with $Ni(CN)_2$ with microwave irradiation to give ArCN.[277] In general, alkali cyanides do convert aryl halides to nitriles[278] in dipolar aprotic solvents in the presence of Pd(II) salts[279] or copper[280] or nickel[281]

complexes. A nickel complex also catalyzes the reaction between aryl triflates and KCN to give aryl nitriles.[282]

Arylthallium bis(trifluoroacetates) (see **12-23**) can be converted to aryl nitriles by treatment with copper(I) cyanide in acetonitrile.[283] Another procedure uses excess aqueous KCN followed by photolysis of the resulting complex ion $ArTl(CN)_3^-$ in the presence of excess KCN.[284] Alternatively, arylthallium acetates react with $Cu(CN)_2$ or CuCN to give aryl nitriles.[285] Yields from this procedure are variable, ranging from almost nothing to 90 or 100%. Aromatic ethers ArOR[286] have been photochemically converted to ArCN.

An indirect method involves the reaction of an aromatic ring with *tert*-butyllithium, particularly when there is a directing group (see **13-17**), followed by reaction with PhOCN (phenyl cyanate) to give the aryl nitrile.[287] another indirect method involve the palladium catalyzed reaction of aryl bromides with the cyanohydrin of acetone $[Me_2C(OH)CN]$ to give ArCN.[288]

OS **III**, 212, 631.

13-9 Coupling of Aryl and Alkyl Organometallic Compounds with Aryl Halides, Ethers, and Carboxylic Esters

Aryl-de-halogenation, and so on

$$\text{Ar–X} + \text{Ar}'\text{–M} \longrightarrow \text{Ar–Ar}'$$

$$\text{Ar–X} + \text{R–M} \longrightarrow \text{Ar–R}$$

A number of methods involving transition metals have been used to prepare unsymmetrical biaryls (see also, **13-11**). The uncatalyzed coupling of aryl halides and metalated aryls (particularly aryllithium reagents) is also known, including cyclization of organolithium reagents to aromatic rings.[289] Noncatalyzed coupling reactions of aryllithium reagents and haloarenes can proceed via the well-known aryne route but in some cases, a novel addition–elimination pathway is possible when substituents facilitate a chelation-driven nucleophilic substitution pathway.[290] Such noncatalyzed coupling reactions often proceed with high regioselectivity and high yield.[290] Several noncatalyzed alternative routes are available. 2-Bromopyridine reacts with pyrrolidine, at 130°C with microwave irradiation, to give 2-(2-pyrrolidino)pyridine.[291] Aryl iodides undergo homo-coupling to give the biaryl by

heating with triethylamine in an ionic liquid.[292] Arylsiloxanes react with aryl halides, for example, to give the biaryl derivative.[293] The reaction of $NaBPh_4$ (sodium tetraphenylborate) and a silyl dichloride (Ph_2SiCl_2) gives biphenyl.[294]

There are many catalytic methods. A homo-coupling type reaction was reported in which $PhSnBu_3$ was treated with 10% $CuCl_2$, 0.5 equivalents of iodine and heated in DMF to give biphenyl.[295] Arylsulfonyl chlorides also react with $ArSnBu_3$ with palladium and copper catalysts to give the biaryl.[296] Aryl halides undergo homo-coupling to give the biaryl with a palladium catalyst[297] or a nickel catalyst.[298] In general, aryl tin compounds couple with aryl halides.[299] An aryltin–aryl halide coupling has been done in ionic liquids.[300] Aryl iodides have been coupled to form symmetric biphenyls using $Pd(OAc)_2$[301] and self-coupling occurs with aryl triflates under electrolysis conditions with a palladium catalyst.[302] A "double-coupling" reaction involving 2-trimethysilylphenol *O*-triflate, allyltributyltin and allyl chloride, with CsF and a palladium catalyst, gave 1,2-diallylbenzene.[303] Another homo-coupling reaction of pyridyl bromides was reported using $NiBr_2$ under electrolytic conditions.[304] Thiophene derivatives,[305] pyrrole,[306] azoles,[307] quinoline,[308] and indolizine[309] have been coupled to aryl halides using a palladium catalyst.

Grignard reagents couple with aryl halides without a palladium catalyst, by the benzyne mechanism,[310] but an iron catalyzed coupling reaction was reported,[311] as

well as a nickel-[312] and a cobalt-catalyzed reaction.[313] The coupling reaction of an excess of a Grignard reagent (RMgX) with methoxy aromatic compounds, when the aromatic ring contains multiple alkoxy groups, proceeds with replacement of the OMe group by R.[314] Aryl Grignard reagents coupled with phenyl allyl sulfone, in the presence of an iron catalyst, to give $ArCH_2CH{=}CH_2$.[315] In a similar manner, aryl sulfone coupled with aryl Grignard reagents in the presence of a nickel catalyst.[316] Arylmagnesium compounds couple to give the symmetrical biaryl in the presence of $TiCl_4$.[317] Arylmagnesium halides couple with aryl tosylates in the presence of a palladium catalyst to give unsymmetrical biaryls,[318] and to halopyridines to give the arylated pyridine.[319] Aryl Grignard reagents can be coupled to aryliodonium salts, with $ZnCl_2$ and a palladium catalyst, to give the biaryl.[320] Specialized aryl bismuth compounds have been used with a palladium catalyst to convert aryl chlorides to biaryls,[321] and specialized alkyl indium complexes have been used with a palladium catalyst to give arenes.[322] α-Lithio lactams are coupled to aryl bromides using a palladium catalyst, giving α-aryl lactams.[323]

The homo-coupling of arylzinc iodides with a palladium catalyst has been reported.[324] Vinyl halides, in the presence of an arylmagnesium halides, $ZnCl_2$ and a palladium catalyst, give the styrene compound.[325] Aryl triflates (halides) couple with ArZn(halide) reagents in the presence of a nickel catalyst.[326] Aryl triflates were coupled to triphenylbismuth using a palladium catalyst.[327] Homo-coupling of triphenylbismuth is known,[328] as well as the coupling of arylbismuth reagents to aryliodonium salts[329] and to aryltin compounds[330] with palladium chloride. Similar coupling was accomplished with aryltellurium compounds.[331] Aryl iodides undergo

a homo-coupling in the presence of hydroquinone and a palladium catalyst.[332] Arylgermanium compounds are coupled with aryl iodides using tetrabutylammonium fluoride and a palladium catalyst.[333] Both alkylmanganese compounds (RMnCl)[334] and Ph_3In[335] react with aryl halides or aryl triflates to give the arene, as do arylbismuth regents with aryl triflates.[336] Aryl halides couple to vinyl acetates, with a cobalt catalyst, to give the styrene derivative.[337] Aryl halides react with cyclopentadiene and Cp_2ZrCl_2 and a palladium catalyst to give pentaphenylcyclopentadiene.[338] Aryl halides also react with phenols to form biaryls using a rhodium catalyst.[339] Diaryliodonium salts react with $PhPb(OAc)_3$ and a palladium catalyst to give the biaryl.[340] Arylsilanes can be coupled to aryl iodides using a palladium catalyst.[341] Aryl halides reacts with acrolein diethyl acetal under electrolysis conditions and a nickel catalyst to give the allyl arene ($Ar{-}CH_2CH{=}CHOEt$).[342]

Unsymmetrical binaphthyls were synthesized by photochemically stimulated reaction of naphthyl iodides with naphthoxide ions in an $S_{RN}1$ reaction.[343] Methyl chloroacetate coupled with aryl iodides under electrolysis conditions, using a nickel catalyst.[344] Unsymmetrical biaryls were prepared from two aryl iodides using a CuI catalyst and microwave irradiation.[345]

Alkylboronic acids are coupled to aryl halides using a palladium catalyst,[346] analogous to the Suzuki reaction in **13-12**. Conversely, arylboronic acids can be coupled to aliphatic halides.[347] Arylboronic acids can be coupled to allylic alcohols as well.[348] Arylboronic acids (**12-28**) were shown to react directly with benzene in the presence of $Mn(OAc)_3$.[349] Arylboronic acids also couple with alkyl halides in

the presence of palladium(II) acetate[350] or a nickel catalyst.[351] Vinylboronic acids coupled to aryl halides to give the vinyl coupling product.[352] Vinylboronic acids have been coupled to aryldiazonium salts (**13-25**) without added base, using a palladium catalyst with an imidazolium ligand.[353]

Alkyltrifluoroborates (RBF_3K, see **12-28**) react with aryl triflates[354] or aryl halides,[355] or aryliodonium salts[356] with a palladium catalyst, to give the arene. The reaction is compatible with sensitive functionality, such as an epoxide unit.

It is possible to couple metalated alkyl compounds to aryl compounds. The lithium enolate anion of an ester was coupled to an aryl halide, for example, using a palladium catalyst.[357]

Chiral vinyl sulfoxides have been coupled to aryl iodides to give a chiral allylic aryl compounds ($C{=}C\text{-}CH_2\text{—}Ar$), in a three-step procedure with good enantioselectivity.[358]

The reaction of a cyclic zirconium–diene complex and an aryl diiodide, with CuCl, leads to highly substituted naphthalene derivatives.[359]

OS **VI**, 916; **VIII**, 430, 586; **X**, 9, 448.

13-10 Arylation and Alkylation of Alkenes

Alkylation or **Alkyl-de-hydrogenation**, and so on

$$R_2C{=}CH_2 \quad + \quad Ar\text{-}X \quad \xrightarrow{Pd(0)} \quad R_2C{=}CH\text{—}Ar$$

Arylation of alkenes can also be achieved[360] by treatment with an "arylpalladium" reagent, typical generated *in situ* from an aryl halide or other suitably functionalized aromatic compound and a palladium(0) catalyst.[361] Other methods

are available for this arylation reaction.[362] Treatment of an arylmercury compound (either Ar_2Hg or ArHgX) with $LiPdCl_3$ (ArHgX → "ArPdX") can generate the appropriate intermediate,[363] and in some cases other noble metal salts have been used. The palladium catalyzed aryl–alkene coupling reaction is known as *the Heck reaction*. The reaction works best with aryl iodides, although conditions have been developed for aryl bromides and aryl chlorides.[364] Aryldiazonium salts (**13-25**), rather than aryl halides, have also been used in the Heck reaction.[365] When 2,3,4,5,6-pentafluorobromobezene was used as a substrate, coupling occurred via the bromine, giving the pentafluorophenyl alkene.[366] Aryl halides bearing ortho-substituents also under the coupling reaction.[367] Heteroaryl halides can be used in the couple reaction.[368] Note that acetanilide derivatives reacted with conjugated esters to give the Heck product in acetic acid using a palladium catalyst.[369] Other activated aromatic compounds couple in a similar manner using palladium catalysts[370] unactivated aromatic compounds using special reaction conditions.[371]

Unlike **13-26**, the Heck reaction is not limited to activated substrates. The substrate can be a simple alkene, or it can contain a variety of functional groups, such as ester, ether,[372,373] carboxyl, phenolic, or cyano groups.[374] Coupling with vinyl ethers has been reported, C=C—OR → C=C(Ar)OR.[375] The Heck reaction can be done with heterocyclic compounds,[376] and the C—C unit of compounds, such as indene, react with aryl iodides and palladium catalyst without the need for

preparing the halide.[377] The Heck reaction has also been performed intramolecularly.[378] Asymmetric Heck reactions are known[379] and the effects of high pressure have been studied.[380]

Ethylene is the most reactive alkene. Increasing substitution lowers the reactivity. Substitution therefore takes place at the less highly substituted side of the double bond.[381] The aryl halide or aryl triflate can be coupled to dienes,[382] allenes,[383] allylic silanes,[384] allylic amines,[385] vinyl phosphonate esters,[386] and with terminal alkynes.[387] Alkylation can also be accomplished, but only if the alkyl group lacks a β-hydrogen, for example, the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.[388] However, vinylic groups, even those possessing β-hydrogens, have been successfully introduced (to give 1,3-dienes) by the reaction of the alkene with a vinylic halide in the presence of a trialkylamine and a palladium(0) catalyst.[389] Aryl iodides can be coupled to 1-methyl-1-vinyl- and 1-methyl-1-(prop-2-enyl)silacyclobutane with desilyation, using a palladium catalyst and Bu_4NF, to give the corresponding styrene derivative.[390] Indene reacts with iodobenzene with a palladium catalyst to give the phenylindene (80:20 C3/C2).[391]

Control of regiochemistry is a serious problem in the addition to unsymmetrical alkenes. Some regioselectivity can be obtained by the use of alkenes attached to an

auxiliary coordinating group,[392] the use of special ligands and acrylate or styrene as substrates.[393] Steric effects are thought to control regioselectivity,[394] but electronic influences have also been proposed.[395] It has been shown that the presence of steric effects generally improve 1,2-selectivity, and that electronic effects can be used to favor 1,2- or 2,1-selectivity.[396]

Phosphine free catalysts[397] and halogen-free reactions[398] are known for the Heck reaction. Improvements on the palladium catalyst system are constantly being reported,[399] including polymer-supported catalysts.[400] The influence of the ligand has been examined.[401] Efforts have been made to produce a homogeneous catalyst for the Heck reaction.[402] The Heck reaction can be done in aq. media,[403] in perfluorinated solvents,[404] in polyethylene glycol,[405] in neat tricaprylmethylammonium

chloride,[406] and in supercritical CO_2 (see p. 414).[407] A noncatalytic reaction was reported using supercritical water.[408] The reaction has been done on solid support,[409] including Montmorillonite clay,[410] glass beads,[411] on a reverse-phase silica support,[412] and using microwave irradiation.[413] A microwave irradiated Heck coupling was done in water using a palladium catalyst.[414] The Heck reaction has also been in ionic liquids,[415] and it is known that the nature of the halide is important in such reactions.[416]

The evidence is in accord with an addition–elimination mechanism (addition of ArPdX followed by elimination of HPdX) in most cases.[417] In the conventionally accepted reaction mechanism,[418] a four-coordinate aryl–Pd(II) intermediate is formed by oxidative addition of the aryl halide to a Pd(0) complex prior to olefin addition. This suggests that cleavage of the dimeric precursor complex, reduction of Pd^{2+}, and ligand dissociation combine to give a viable catalytic species.[419] If these processes occur on a time scale comparable to that of the catalytic reaction, nonsteady-state catalysis could occur while the active catalyst is forming, and an

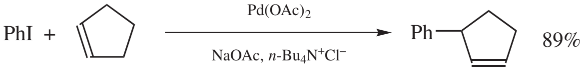
analysis of reaction kinetics under dry conditions was reported.[419] In this study, the mechanism requires a first-order dependence on olefin concentration, and anomalous kinetics may be observed when the rate-limiting step is not directly on the catalytic cycle.[419]



21

$$CH_2{=}CH{-}CH_2OH \xrightarrow{\text{"PdPdCl"}} PhCH_2CH_2CHO$$

22

The reactions are stereospecific, yielding products expected from syn addition followed by syn elimination.[420] Because the product is formed by an elimination step, with suitable substrates double bond migration can occur, resulting in allylic rearrangement (as in the reaction of cyclopentene and iodobenzene to give **21**).[421] Primary and secondary allylic alcohols (and even non-allylic unsaturated alcohols[422]) give aldehydes, such as **22** or ketones that are products of double-bond migration.[423] Similarly, dihydrofurans react with aryl triflates and a palladium catalyst that includes a chiral ligand, to give the 5-phenyl-3,4-dihydrofuran with good enantioselectivity.[424] A similar reaction was reported for an *N*-carbamoyl dihydropyrrole.[425] It has been reported that double bond isomerization can be suppressed in intramolecular Heck reactions done in supercritical CO_2 (see p. 414).[426] The mechanistic implications of asymmetric Heck reactions has been examined.[427]

There are a number of variations of this reaction, including the use of transition metal catalyst other than palladium. A silane-tethered, intramolecular Heck reaction has been reported.[428] Arylphosphonic acids, $ArP(=O)(OH)_2$, couple to aryl alkenes in the presence of a palladium catalyst.[429] Aryl halides couple with vinyl

tin reagents to form styrene derivatives in the presence of a nickel catalyst.[430] Aryl chlorides were coupled to conjugated esters using a $RuCl_3 \cdot 3\ H_2O$, in an atmosphere of O_2 and CO.[431] Alkenyl organometallic compounds have been coupled to aryl halides, including allenyltin compounds ($C{=}C{=}C\text{-}SnR_3$).[432] Divinylindium chloride, $(CH_2{=}CH)_2InCl$, reacted with an aryl iodide in aq. THF with a palladium catalyst to give the styrene derivative.[433] Trialkenylindium reagents reacted similarly with aryl halides and a palladium catalyst.[434] Arylzinc chlorides (ArZncl) were coupled to vinyl chlorides using a palladium catalyst,[435] and vinyl zinc compounds were coupled to aryl iodides.[436] Aryliodonium salts can be coupled to conjugated alkenes in a Heck-like manner using a palladium catalyst.[437] In the presence of trimethylsilylmagnesium chloride, primary alkyl halides coupled to aryl alkenes to give the substituted alkene (R′—CH=CHAr), using a cobalt catalyst.[438]

Arylboronic acids (**12-28**) have been coupled to conjugated alkenes to give the aryl–alkene coupling product using a palladium catalyst,[439] a ruthenium catalyst with copper(II) acetate,[440] or a rhodium catalyst.[441] Arylboronic acids have also been coupled to vinyl halides[442] or vinyl tosylates[443] using a palladium catalyst. Note that the reaction of an arylboronic acid and 1,2-dibromoethane, with KOH and a palladium catalyst leads to the styrene derivative.[444] vinylboronic acids have been coupled to aryl halides using a palladium catalyst.[445] Styrene derivatives have been prepared by the reaction of aryl halides and 2,4,6-trivinylcyclotriboroxane, with a palladium catalyst.[446] Conjugated esters can be coupled to benzene using a palladium acetate/benzoquinone catalyst, *tert*-butyl hydroperoxide in acetic acid–acetic anhydride, at 90°C in a sealed tube.[447] Vinyl silanes were converted to styrene derivatives upon treatment with Bu_4NF, and aryl iodide and a palladium

catalyst.[448] Arylsilanes were coupled to alkenes to give the styrene derivative using palladium acetate and an oxygen atmosphere,[449] for Bu_4NF and an iridium catalyst.[450]

In a related reaction, vinyltrifluoroborates $C{=}C\text{-}BF_3^+\ X^-$ (**12-28**), are coupled to aryl halides with a palladium catalyst to give the styrene derivative.[451]

In an unusual variation, an aryl compound bearing a tertiary alcohol substituent ($ArCMe_2OH$) reacted with aryl halides and a palladium catalyst to give the biaryl.[452] Benzoyl chloride was coupled to styrene to form PhCH=CHPh using a rhodium catalyst.[453] Benzoic acid was coupled to styrene to give the same type of product using a palladium catalyst and a diacyl peroxide.[454]

13-11 Homo-Coupling of Aryl Halides: The Ullmann Reaction

De-halogen-coupling

$$2\ \mathrm{ArI} \xrightarrow[\Delta]{\mathrm{Cu}} \mathrm{Ar{-}Ar}$$

The coupling of aryl halides with copper is called the *Ullmann reaction*.[455] The reaction is clearly related to **13-9**, but involves aryl copper intermediates. The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.[456] When a mixture of two different aryl halides is used, there are three possible products, but often only one is obtained. For example, picryl chloride and iodobenzene gave only 2,4,6-trinitrobiphenyl.[457] The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used.

The effects of other groups on the ring are unusual. The nitro group is strongly activating, but only in the ortho (not meta or para) position.[458] Both R and OR groups activate in all positions. Not only do OH, NH_2, NHR, and NHCOR inhibit

the reaction, as would be expected for aromatic nucleophilic substitution, but so do COOH (but not COOR), SO_2NH_2, and similar groups for which the reaction fails completely. These groups inhibit the coupling reaction by causing side reactions.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the Wurtz reaction (**10-56**), which can be represented schematically by

Step 1 ArI + Cu ⟶ ArCu

Step 2 ArCu + ArI ⟶ Ar—Ar

Organocopper compounds have been trapped by coordination with organic bases.[459] In addition, aryl copper compounds (ArCu) have been independently prepared and shown to give biaryls (Ar—Ar') when treated with aryl iodides Ar'I.[460] A similar reaction has been used for ring closure:[461]

An important alternative to the Ullmann method is the use of certain nickel complexes.[462] This method has also been used intramolecularly.[463] Aryl halides ArX can also be converted to Ar—Ar[464] by treatment with activated Ni metal,[465] with Zn and nickel complexes,[466] with aqueous alkaline sodium formate, Pd—C, and a phase-transfer catalyst,[467] and in an electrochemical process catalyzed by a nickel complex.[468]

An asymmetric Ullmann reaction has also been reported.[469]

The palladium-catalyzed coupling of aryl halides and other aryl substrates with aromatic rings containing a suitable leaving group is now well established. Other nucleophiles can be coupled to aryl halides.[470] The reaction has become so significant in organic chemistry that the transformations have been categorized as named reactions, and are discussed in Sections **13-14** and **13-15**.

13-12 Coupling of Aryl Compounds With Arylboronic acid Derivatives

Aryl-de-halogenation, and so on **Aryl-de-boronylation**, and so on

$$\text{Ar—Br} \quad + \quad \text{Ar}'\text{B(OH)}_2 \xrightarrow{\text{PdL}_4} \text{Ar—Ar}'$$

Aryl triflates react with arylboronic acids, $ArB(OH)_2$ (**12-28**),[471] or with organoboranes,[472] in the presence of a palladium catalyst,[473] to give the arene in what is called *Suzuki coupling* (or *Suzuki–Miyaura coupling*).[474] Aryl halides are commonly used, and aryl sulfonates have been used.[475] Even hindered boronic acids give good yields of the coupled product.[476] Homo-coupling of arylboronic acids has been reported.[477] Coupling of the alkynes to form a diyne (see **14-16**) can be a problem is some cases, although the aryl–alkyne coupling usually predominates.[478] Some aromatic compounds are so reactive that a catalyst may not be required. Using tetrabutylammonium bromide, phenylboronic acid was coupled to 2-bromofuran without a catalyst.[479]

Different conditions (including additives and solvent) for the reaction have been reported,[480] often focusing on the palladium catalyst itself,[481] or the ligand.[482] Catalysts have been developed for deactivated aryl chlorides,[483] and nickel catalysts have been used.[484] Modifications to the basic procedure include tethering the aryl triflate[485] or the boronic acid[486] to a polymer, allowing a polymer-supported Suzuki reaction. Polymer-bound palladium complexes have also been used.[487,488] The reaction has been done neat on alumina,[489] and on alumina with microwave irradiation.[490] Suzuki coupling has also been done in ionic liquids,[491] in supercritical

CO_2[492] (see p. 414), and in water with microwave irradiation[493] or in water with a palladium catalyst, air, and tetrabutylammonium fluoride.[494] A solvent free (neat) Suzuki reactions have been reported.[495] A variety of functional groups are compatible with Suzuki coupling, including $Ar_2P{=}O$,[496] CHO,[497] C=O of a ketone,[498] CO_2R,[499] cyclopropyl,[500] NO_2,[501] CN,[488] and halogen substituents.[502]

There are many structural variations of the reaction that give it enormous synthetic potential. Halogenated heteroaromatic compounds react. 2-Halopyridines react with arylboronic acids and a palladium catalyst to give 2-arylpyridines.[503] Other heterocycles have been similarly arylated.[504] 4-Pyridylboronic acids have been used.[505] The reaction of phenylboronic acid and a diallyl amide which contained a vinyl bromide, led to ring closure as well as incorporation of the phenyl group, give an *N*-tosylpyrrolidine with an exocyclic methylene unit.[506] Vinyl halides react with arylboronic acids to give alkenyl derivatives (vinyl arenes, C=C—Ar).[507] Alkylation can accompany arylation if alkyl halides are added, as in the conversion of iodobenzene to 2,6-dibutylbiphenyl.[508]

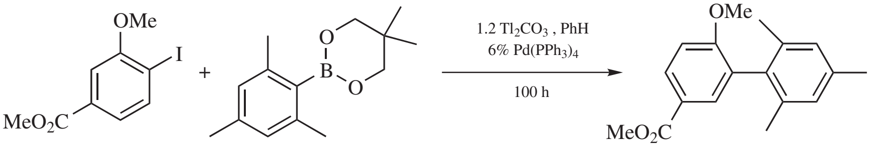
Since many biaryls are chiral due to atropisomerism (see p. 147), the use of a chiral catalyst, and/or a chiral ligand can lead to enantioselectivity in the Suzuki coupling.[509]

Arylsulfonates can be coupled to aryl triflates using a palladium catalyst,[510] and arylboronic acids couple with aryl sulfonate esters.[511] Aryl boronic acids are coupled with aryl ammonium salts to give the biaryl, with a nickel catalyst.[512] Allylic acetates have been coupled to arylboronic acids using nickel bis(acetylacetonate) and diisobutylaluminum hydride.[513] Aryl halides couple with $ArB(IR'_2)$ species with a palladium catalyst.[514] Arylboronic acids couple with the phenyl group of Ph_2TeCl_2 with a palladium catalyst.[515] 3-Iodopyridine reacted with NaBPh and palladium acetate, with microwave irradiation, to give 3-phenylpyridine.[516] Tributyltinaryl compounds were coupled to the aryl group of $Ar_2I^+BF_4^-$ with a nickel catalyst.[517] Organoboranes are coupled to aryl halides with a palladium catalyst.[518] Aryl silanes can be coupled to aryl iodides using Ag_2O and a palladium catalyst,[519] and arylsiloxanes $ArSi(OR)_3$, are coupled to aryl halides with Bu_4NF and a palladium catalyst.[520]

Arylborates (**12-28**), $ArB(OR)_2$, can be used in place of the boronic acid. The coupling reaction of aryl iodide **23** with boronate **24**, for example, gave the biaryl.[521] Aryl and heteroarylboroxines (**25**) can be coupled to aryl halides using a palladium catalyst.[522]



23 **24**

For a mechanistic viewpoint,[523] the Suzuki coupling proceeds via oxidative addition of areneboronic acids to give a Pd(0) species, followed by 1,2 arene migration to an electron-deficient palladium atom, eventually leading to very fast reductive

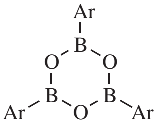
elimination to afford biaryls.[524] Several intermediates of the oxidative coupling process have been identified by electrospray ionization mass spectrometry.[525]



25

A Suzuki-type coupling reaction has been reported involving acyl halides. When arylboronic acids were reacted with benzoyl chloride and $PdCl_2$, the product was the diaryl ketone.[526] This coupling reaction was also accomplished using a palladium(0) catalyst.[527] Cyclopropylboronic acids couple with benzoyl chloride, in the presence of Ag_2O and a palladium catalyst, to give the cyclopropyl ketone.[528] A nickel catalyst has been used,[529] and Ph_3P/Ni/C—BuLi has also been used.[530] Arylboronic acids have also been coupled to anhydrides,[531] and the methoxy group of anisole derivatives has been replaced with phenyl using phenylboronic acid and a ruthenium catalyst.[532]

In a related reaction, aryltrifluoroborates $PhBF_3^+ X^-$ (**12-28**), are coupled to aryl halides with a palladium catalyst to give the biaryl.[533]

OS **75**, 53, 61

The coupling reactions of alkylboronic acids are covered in **13-17**.

OS X, 102, 467; **81**, 89.

13-13 Aryl–Alkyne Coupling Reactions

Alkynyl-de-halogenation, and so on

$$ArI + RC{\equiv}CCu \longrightarrow ArC{\equiv}CR$$

When aryl halides react with copper acetylides to give 1-aryl alkynes, the reaction is known as *Stephens–Castro coupling*.[534] Both aliphatic and aromatic

substituents can be attached to the alkyne unit, and a variety of aryl iodides has been used. Benzonitrile was shown to react with alkynyl zinc bromides, with a nickel catalyst and after electrolysis to give the diarylalkyne, where the cyano unit was replaced with an alkyne unit.[535]

$$\text{Ar-X} + \text{RC}{\equiv}\text{CH} \xrightarrow{\text{Pd(0)}} \text{Ar-C}{\equiv}\text{CR}$$

A palladium–catalyzed variation is also known in which an aryl halide reacts with a terminal alkyne to give 1-aryl alkynes is called the *Sonogashira coupling*.[536] Terminal aryl alkynes react with aryl iodides and palladium(0)[537] to give the corresponding diaryl alkyne.[538] As with all of the metal-catalyzed reactions in this chapter, work has been done to vary reaction conditions, including the catalyst,[539] the ligand, the solvent,[540] and additives.[541] copper-free palladium/DABCO catalysts have been used.[542] Aryl iodides are more reactive than aryl fluorides.[543] Alkynes can be coupled to heteroaromatic compounds via the heteroaryl halide.[544] The coupling reaction has been done neat, with microwave irradiation on KF-alumina,[545] and in aqueous polyethylene glycol.[546] The aryl–alkyne coupling has also been done in solution with microwave irradiation.[547] Sonogashira coupling

was reported on microbeads,[548] with nanoparticulate nickel powder,[549] and the aryl iodide was tethered to a polymer for a solid-state reaction that included the use of microwave irradiation, and cleavage from the polymer using trifluoroacetic acid.[550] Polymer supported catalysts are known.[551] Conversion of 1-lithioalkynes to the corresponding alkynyl zinc reagent allows coupling with aryl iodides when a palladium catalyst is used.[552] Coupling with alkynyl tin compounds is also known.[553] The 1-lithioalkyne was directly coupled to aryl bromides in the presence of $B(OiPr)_3$ and a palladium catalyst,[554] where an alkynylboronic acid was generated *in situ*.

A variation was reported with environmental importance, where the triphenylphosphine by-product was scavenged by addition of Merrifield resin.[555] A copper-free Sonogashira coupling has been reported, in triethylamine[556] and in an ionic liquid.[557] A copper and amine-free reaction was reported in normal solvents, such as THF.[558] An interesting example of the versatility of the coupling reaction is the coupling of propargyl bromide and an aryl iodide, in the presence of an amine, giving the aryl aminomethylalkyne.[559] The coupling of 4-chloroacetophenone with 1-phenylethyne shows that the carbonyl group is compatible with this reaction.[560]

Diaryliodonium salts react with terminal alkynes to give the phenyl alkyne.[561] A variation couples the phenyl group of $Ph_2I^+OTf^-$ with an en-yne using a palladium catalyst.[562] Aryl sulfonate esters can be coupled to terminal alkynes using a palladium catalyst in polymethylhydrosiloxane.[563] Aryl halides are coupled to alkynyltrifluoroborates ($R{-}C{\equiv}C{-}BF_3K$, **12-28**) using a palladium catalyst.[564] The boron trifluoride induced palladium-catalyzed cross-coupling reaction of 1-aryltriazenes with areneboronic acids has been reported.[565]

A variation of this aryl–alkyne coupling reaction reacted methylthioalkynes ($R{-}C{\equiv}C{-}SMe$) with arylboronic acids and a palladium catalyst to give the aryl alkyne ($R{-}C{\equiv}C{-}Ar$).[566] 1-Trialkylsilylalkynes ($R_3Si{-}C{\equiv}C{-}R'$) were coupled

to aryl iodides using a palladium catalyst.[567] A triphenylstibine, $Ph_3Sb(OAc)_2$, was used to transfer a phenyl group to the alkyne carbon of PhC≡$CSiMe_3$, using palladium and CuI catalysts.[568] Aryl iodides were also coupled to lithium alkynyl borate complexes, Li[R—C≡C—B(OR′)$_3$], to give the aryl alkyne.[569] Note that diphenylethyne was prepared from bromobenzene and 2-chloro-1-bromoethane using KOH, 18-crown-6 and a palladium catalyst.[570]

13-14 Arylation at a Carbon Containing an Active Hydrogen

Bis(ethoxycarbonyl)methyl-de-halogenation, and so on

The arylation of compounds of the form ZCH_2Z' is analogous to **10-67**, where Z is as defined as an electron withdrawing group (ester, cyano, sulfonyl, etc.). Activated aryl halides generally give good results.[571] Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base, such as $NaNH_2$[572] or LDA. Compounds of the form ZCH_2Z', even simple ketones[573] and carboxylic esters have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: it removes a proton from ZCH_2Z' and catalyzes the benzyne mechanism. The reaction has been used for ring closure, as in the formation of **26**.[574]

The coupling of active methylene compounds and unactivated aryl halides can also be done with copper halide catalysts[93] (the *Hurtley reaction*).[575] A palladium catalyst can be used for the coupling of malonate esters with unactivated aryl halides.[576] Bis(sulfones), $CH_2(SO_2Ar)_2$, react with aryl halides in the presence of a palladium catalyst.[577] Similar coupling was accomplished with $CH_2(CN)_2$ and a nickel catalyst.[578] Malonic and β-keto esters can be arylated at the α-carbon in high yields by treatment with aryllead tricarboxylates [$ArPb(OAc)_3$],[579] and with triphenylbismuth carbonate (Ph_3BiCO_3)[580] and other bismuth reagents.[581] In a related process, manganese(III) acetate was used to convert a mixture of ArH and ZCH_2Z' to ArCHZZ′.[582]

The reaction of the enolate anions ketones and aldehydes, generated *in situ* by addition of a suitable base, with aryl halides can be accomplished by treatment with a palladium catalyst.[583] Formation of an enolate anion of a conjugated ketone (cyclohexenone) via reaction with LDA (see p. 389), in the presence of Ph_3BiCl_2, leads to the α-phenyl conjugated ketone (6-phenylcyclohex-2-enone).[584] An ester reacted with $TiCl_4$ and *N,N*-dimethylanline to give the para-substitution product. (Me_2N—Ar—$CHRCO_2Et$).[585] The enolate anion of lactams will react with aryl halides in the presence of a palladium catalyst go via the 3-aryl lactam.[586] When the enolate anion of a ketone is generated in the presence of a palladium catalyst and a chiral phosphine ligand, the α-aryl ketone is formed with good enantioselectivity.[587]

Compounds of the form CH_3Z can be arylated by treatment with an aryl halide in liquid ammonia containing Na or K, as in the formation of **27** and **28**.[588]

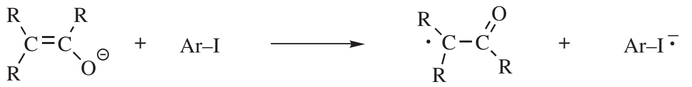
27 **28**

When the solution is irradiated with near-UV light, but Na or K is omitted, the same products are obtained (though in different proportions).[589] In either case, other leaving groups can be used instead of halogens (e.g., NR_3^+, SAr) and the mechanism is the $S_{RN}1$ mechanism. Iron(II) salts have also been used to initiate this reaction.[590] The reaction can also take place without an added initiator. The reaction of 2-fluoroanisole and KHMDS, and 4 equivalents of 2-cyanopropane, leads to substitution of the fluorine atom by CMe_2CN.[591] A similar reaction as reported using a palladium catalyst.[592] Nitroethane was converted to 2-phenylnitroethane using bromobenzene and a palladium catalyst.[593]

Enolate ions of ketones react with PhI in the dark.[594] In this case, it has been suggested[595] that initiation takes place by formation of a radical, such as **29**.



29

This is an SET mechanism (see p. 444). The photostimulated reaction has also been used for ring closure.[596] In certain instances of the intermolecular reaction there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.[597]

Alkoxycarbonyl-de-halogenation, and so on

$$\text{ArX} + \text{CO} + \text{ROH} \xrightarrow[\text{Pd complex}]{\text{base}} \text{ArCOOR}$$

Carbonylation of aryl bromides and iodides with carbon monoxide, an alcohol, a base, and a palladium catalyst, give carboxylic esters. Even very sterically hindered alkoxides can be used to produce the corresponding ester.[599] The use of H_2O, RNH_2, or an alkali metal or calcium carboxylate[600] instead of ROH, gives the carboxylic acid,[601] amide,[602] or mixed anhydride, respectively.[603] Heating an aryl iodide, CO in ethanol and DBU, with a palladium catalyst, gave the ethyl ester of the aryl carboxylic acid.[604] A similar result was obtained when an aryl iodide was heated in ethanol with triethylamine, CO and Pd/C.[605] Ester formation via carbonylation was done is supercritical CO_2 (see p. 414).[606] With certain palladium catalysts, aryl chlorides[607] and aryl triflates[608] can also be substrates. Aryl carboxylic acids were also prepared from aryl iodides by heating in DMF with lithium formate, LiCl, acetic anhydride and a palladium catalyst.[609] A silica-supported palladium reagent has been used to convert iodobenzene to butyl benzoate, in the presence of CO and butanol.[610] 2-Chloropyridine was converted the butyl pyridine 2-carboxylate with this procedure.[611] Halogenated biaryls can be converted to the tricyclic ketone, 9-fluorenone, by an intramolecular carbonylation reaction with CO and a palladium catalyst.[612] A surrogate reagent used instead of CO is dicobalt octacarbonyl $CO_2(CO)_8$.[613] Aryl chlorides have been converted to carboxylic acids by an electrochemical synthesis,[614] and aryl iodides to aldehydes by treatment with

CO, Bu_3SnH, and $NCCMe_2N{=}NCMe_2CN$ (AIBN).[615] Aryl ketones can be prepared from aryltrimethylsilanes $ArSiMe_3$ and acyl chlorides in the presence of $AlCl_3$.[616] Aryllithium and Grignard reagents react with iron pentacarbonyl to give aldehydes ArCHO.[617] The reaction of CO with aryllithium may occur by electron transfer.[618]

Aryl iodides are converted to unsymmetrical diaryl ketones on treatment with arylmercury halides and nickel carbonyl: $ArI + Ar'HgX + Ni(CO)_4 \rightarrow ArCOAr'$.[619] Aryl iodides are carbonylated to give the aryl alkyl ketone with CO and R_3In.[620] Arylthallium bis(trifluoroacetates), $ArTl(O_2CCF_3)_2$ (see **12-23**), can be carbonylated with CO, an alcohol, and a $PdCl_2$ catalyst to give esters.[621] Organomercury compounds undergo a similar reaction.[622] The aryllead reagent $PhPb(OAc)_3$, was converted to benzophenone using NaOMe, CO and a palladium catalyst.[623] Aryl iodides containing an ortho substituent with a β-cyano group that served as the source of a carbonyl group, was converted to a bicyclic ketone with a palladium catalyst at 130°C in aqueous DMF.[624]

Diaryl ketones can also be prepared by coupling aryl iodides with phenylboronic acid (**12-28**), in the presence of CO and a palladium catalyst.[625] This reaction has been extended to heteroaromatic systems, with the preparation of phenyl 4-pyridyl ketone from phenylboronic acid and 4-iodopyridine.[626] 2-Bromopyridine as coupled with phenylboronic acid, CO and a palladium catalyst to give phenyl 2-pyridyl ketone.[627] An interesting reaction treated a titanocycle (**30**) with CO to give the cyclobutanone.[628] Carbonylation of an alkyne and an aryl halide, with CO

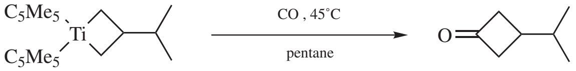
and palladium and copper catalysts, gave the alkynyl ketone RC≡C(C=O)Ar.[629]



30

Note that seleno esters (ArCOSeAr) were prepared from aryl iodides, CO, $PhSeSnBu_3$, and a palladium catalyst.[630]

13-16 Arylation of Silanes

Silyl and Silyloxy-de-halogenation, and so on

$$\text{Ar–X} \quad + \quad \text{Ar}'\text{SiR}_2 \longrightarrow \text{Ar–SiR}_3$$

In the presence of transition-metal catalysts, such as palladium, trialkoxysilanes [$HSi(OR)_3$] react with aryl halides to give the corresponding arylsilane.[631] This transformation is an alternative to the Suzuki coupling (**13-10**).[632] A similar reaction was reported using a rhodium catalyst.[633] Arylsilanes can be coupled to aryl iodides in aqueous media.[634] Arylsilanes react with alkyl halides to give the corresponding arene, in the presence of a palladium catalyst.[635] Suzuki-type coupling using $Me_3SiSiMe_3$ leads to aryl silanes.[636]

An alternative approach reacts aryllithium reagents with siloxanes [$Si(OR)_4$], to give the aryl derivative $ArSi(OR)_3$.[637]

HYDROGEN AS LEAVING GROUP[638]

13-17 Alkylation and Arylation

Alkylation or Alkyl-de-hydrogenation, and so on

The alkylation of aromatic rings was introduced, in part, in section **10-57**. The reaction of an aromatic ring with an organolithium reagent can give H—Li exchange to form an aryllithium. This reaction tends to be slow in the absence of diamine additives or if there are activating substituents on the aryl halide.[639] When heteroatom substituents are present as in **31**, however, the reaction is facile and the lithium goes into the 2 position (as in **32**).[640] This regioselectivity can be quite valuable synthetically, and is now known as *directed ortho metalation*[641] (see **10-57**). Lithiation reactions do not necessarily rely on a complex-induced proximity effect.[642] With TMEDA/*n*-butyllithium-mediate arene lithiation reactions, the viability of directive effects (complex-induced proximate effects) has been questioned,[643] although it is not clear if this extends to other systems (particularly when there is a strong coordinating group, such as carbamate).[644] The 2 position is much more acidic than the 3 position (see Table 8.1), but a negative charge at C-3 is in a more favorable position to be stabilized by the Li^+. Formation of the ortho arylmagnesium compound has been accomplished with bases of the form $(R_2N)_2Mg$.[645] Note that H—Li exchange can be faster than Cl—Li exchange. Treatment of 2-chloro-5-phenylpyridine with *tert*-butyllithium leads to lithiation on the phenyl ring rather than Li—Cl exchange, and subsequent treatment with dimethyl sulfate gave 2-chloro-5-(2-methylphenyl)pyridine.[646] Heteroaromatic rings do react, however. The reaction of 2-chloropyridine with 3 equivalents of butyllithium-$Me_2NCH_2CH_2OLi$ and then iodomethane gave 2-chloro-6-methylpyridine.[647] The reaction of *N*-triisopropylsilyl indole with *tert*-butyllithium and then iodomethane gave the 3-methyl derivative.[648] Furfural (furan 2-carboxaldehyde) reacts with aryl iodides in the presence of a palladium catalyst to give the 5-arylfuran 2-carboxaldehyde.[649]

Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithium reagents, though the usual reaction with these reagents is **12-22**,[650] and Grignard reagents have been used to alkylate naphthalene.[651] The addition–elimination

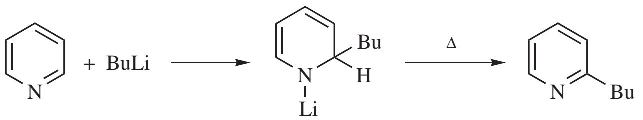
mechanism apparently applies in these cases too. A protected form of benzaldehyde (protected as the benzyl imine) has been similarly alkylated at the *ortho*-position with butyllithium.[652]



The alkylation of heterocyclic nitrogen compounds[653] with alkyllithium reagents is called *Ziegler alkylation*. Aryllithium reagents give arylation. The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.[654] Upon heating of the adduct, elimination of LiH occurs and an alkylated product is obtained. With respect to the 2-carbon the first step is the same as that of the S_NAr mechanism. The difference is that the unshared pair of electrons on the nitrogen combines with the lithium, so the extra pair of ring electrons has a place to go: it becomes the new unshared pair on the nitrogen. Heteroaromatic compounds can be alkylated. Pyrrole, for example, reacts with an allylic halide and zinc to give primarily the 3-substituted pyrrole.[655]

Mercuration of aromatic compounds[656] can be accomplished with mercuric salts, most often $Hg(OAc)_2$[657] to give ArHgOAc. This is ordinary electrophilic aromatic substitution and takes place by the arenium ion mechanism (p. 657).[658] Aromatic compounds can also be converted to arylthallium bis(trifluoroacetates) $ArTl(OOCCF_3)_2$ by treatment with thallium(III) trifluoroacetate[659] in trifluoroacetic acid.[660] These arylthallium compounds can be converted to phenols, aryl iodides or fluorides (**12-31**), aryl cyanides (**12-34**), aryl nitro compounds,[661] or aryl esters

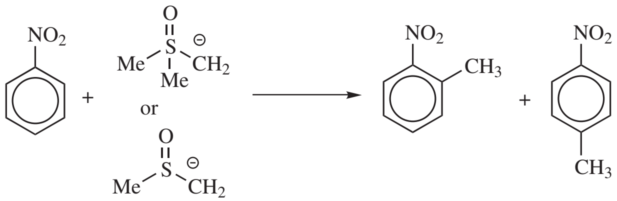
(**12-33**). The mechanism of thallation appears to be complex, with electrophilic and electron-transfer mechanisms both taking place.[662] Transient metalated aryl complexes can be formed that react with another aromatic compound. Aryl iodides reacted with benzene to form a biaryl in the presence of an iridium catalyst.[663] Aniline derivatives reacted with $TiCl_4$ to give the para-homo coupling product (R_2N—Ar—Ar—NR_2).[664]

Aromatic nitro compounds can be methylated with dimethyloxosulfonium methylid[665] or the methylsulfinyl carbanion (obtained by treatment of DMSO with a strong base):[666]



The latter reagent also methylates certain heterocyclic compounds (e.g., quinoline) and certain fused aromatic compounds (e.g., anthracene, phenanthrene).[666,667] The reactions with the sulfur carbanions are especially useful, since none of these substrates can be methylated by the Friedel–Crafts procedure (**11-10**). It has been reported[668] that aromatic nitro compounds can also be alkylated, not only with methyl but with other alkyl and substituted alkyl groups as well, in ortho and para positions, by treatment with an alkyllithium compound (or, with lower yields, a Grignard reagent), followed by an oxidizing agent, such as Br_2 or DDQ (p. 1710).

A different kind of alkylation of nitro compounds uses carbanion nucleophiles that have a chlorine at the carbanionic carbon. The following process takes place:[669]

[669]In some cases, the intermediate bearing the CHCl(Z) unit has been isolated: Stahly, G.P.; Stahly, B.C.; Maloney, J.R. *J. Org. Chem.* ***1988***, *53*, 690.

This type of process is called *vicarious nucleophilic substitution of hydrogen*.[670] The Z group is electron -withdrawing (e.g., SO_2R, SO_2OR, SO_2NR_2, COOR, or CN); it stabilizes the negative charge. The carbanion attacks the activated ring ortho or para to the nitro group.[671] Hydride ion H^- is not normally a leaving group, but in this case the presence of the adjacent Cl allows the hydrogen to be replaced. Hence, Cl is a "vicarious" leaving group. Other leaving groups have been used (e.g., OMe, SPh), but Cl is generally the best. Many groups W in ortho, meta, or para positions do not interfere. The reaction is also successful for di- and trinitro compounds, for nitronaphthalenes,[672] and for many nitro heterocycles. Z—$^{\ominus}$CR–Cl may also be used.[673] When Br_3C^- or Cl_3C^- is the nucleophile the product is $ArCHX_2$, which can easily be hydrolyzed to ArCHO.[674] This is therefore an indirect way of formylating an aromatic ring containing one or more NO_2 groups, which cannot be done by any of the formylations mentioned in Chapter 11 (**11-1–11-18**).

Replacement of an amino group is possible. When aniline derivatives were treated with allyl bromide and *tert*-butyl nitrite (*t*-BuONO), the aryl–allyl coupling product was formed ($Ar{-}NH_2 \rightarrow Ar{-}CH_2CH{=}CH_2$).[675]

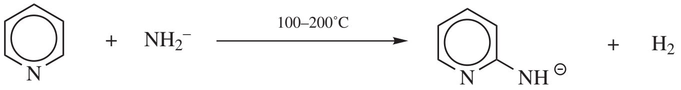
OS **II**, 517.

13-18 Amination of Nitrogen Heterocycles

Amination or **Amino-de-hydrogenation**



Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali-metal amides in a process called the *Chichibabin reaction*.[676] The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali-metal amides (e.g., RNH^- and R_2N^-) have also been used. The mechanism is probably similar to that of **13-17** The existence of intermediate ions, such as **33**

33

(from quinoline) has been demonstrated by NMR spectra.[677] A pyridyne type of intermediate was ruled out by several observations including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine[678] and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,[679] but they have been aminated (ArH $\rightarrow$ $ArNH_2$ or ArNHR) via the vicarious substitution principle (see **13-17**), using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.[680] The vicarious leaving group in this case is the triazole ring. Note, however, that 3-nitropyridine was converted to 6-amino-3-nitropyridine by reaction with KOH, hydroxylamine and $ZnCl_2$.[681]

Analogous reactions have been carried out with hydrazide ions, R_2NNH^-.[682] A mixture of NO_2 and O_3, with excess $NaHSO_3$, converted pyridine to 3-aminopyridine.[683] For other methods of aminating aromatic rings, see **11-6**.

There are no *Organic Syntheses* references, but see OS **V**, 977, for a related reaction.

NITROGEN AS LEAVING GROUP

The diazonium group can be replaced by a number of groups.[684] Some of these are nucleophilic substitutions, with S_N1 mechanisms (p. 432), but others are free-radical reactions and are treated in Chapter 14. The solvent in all these reactions is usually water. With other solvents it has been shown that the S_N1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free-radical mechanisms.[685] The N_2^+ group[686] can be replaced by Cl^-, Br^-, and CN^-, by a nucleophilic mechanism (see OS **IV**, 182), but the Sandmeyer reaction is much more useful (**14-20**). Transition metal catalyzed reactions are known involving aryldiazonium salts, and diazonium variants of the Heck reaction (**13-10**) and Suzuki coupling (**13-12**) were discussed previously. As mentioned on p. 866 it must be

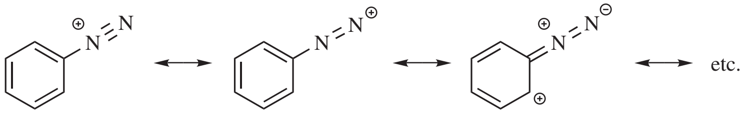
kept in mind that the N_2^+ group can activate the removal of another group on the ring. In a few cases, nitrogen groups, such as nitro or ammonium can be replaced.

13-19 Diazotization

$$\text{Ar—NH}_2 \;+\; \text{HONO} \longrightarrow \text{Ar}-\overset{\oplus}{\text{N}}\equiv\text{N}$$

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.[687] The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (see p. 500). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogens and the ring:



34 **35**

Incidentally, **34** contributes more to the hybrid than **35**, as shown by bond-distance measurements.[688] In benzenediazonium chloride, the C—N distance is ~1.42 Å, and the N—N distance ~1.08 Å,[689] which values fit more closely to a single and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are stable only at low temperatures, usually only $< 5°C$, although more stable ones, such as the diazonium salt obtained from sulfanilic acid, are stable up to 10 or 15°C. Diazonium salts are usually prepared in aqueous solution and used without isolation,[690] although it is possible to prepare solid diazonium salts if desired (see **13-23**). The stability of aryl diazonium salts can be increased by crown ether complexion.[691]

For aromatic amines, the reaction is very general. Halogen, nitro, alkyl, aldehyde, sulfonic acid, and so on, groups do not interfere. Since aliphatic amines do not react with

nitrous acid below a pH ∼ 3, it is even possible, by working at a pH ∼ 1, to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.[692]

$$EtOOC—CH_2—NH_2 \;+\; HONO \longrightarrow EtOOC—CH{=}\overset{\oplus}{N}{=}N$$

If an aliphatic amino group is a to a COOR, CN, CHO, COR, and so on, and has an a hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound*.[693] Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite and a small amount of acid.[694] Certain heterocyclic amines also give diazo compounds rather than diazonium salts.[695]

Despite the fact that diazotization takes place in acid solution, the actual species attacked is not the salt of the amine, but the small amount of free amine present.[696] It is because aliphatic amines are stronger bases than aromatic ones that at pH values < 3 there is not enough free amine present for the former to be diazotized, while the latter still undergo the reaction. In dilute acid the actual attacking species is N_2O_3, which acts as a carrier of NO^+. Evidence is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.[697] Under these conditions the mechanism is

There exists other evidence for this mechanism.[698] Other attacking species can be NOCl, $H_2NO_2^+$, and at high acidities even NO^+. Nucleophiles (e.g., Cl^-, SCN^-, thiourea) catalyze the reaction by converting the HONO to a better electrophile (e.g., $HNO_2 + Cl^- + H^+ \rightarrow NOCl + H_2O$).[699]

N-Aryl ureas are converted to the aryldiazonium nitrate upon treatment with $NaNO_2$ and H_2SO_4 in dioxane[700] or with DMF—NO_2 in DMF.[701]

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. We do not list them here, but under reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III**, 392; **IV**, 424. See also, OS **VI**, 840.

13-20 Hydroxylation of Aryldiazonium Salts

Hydroxy-de-diazoniation

$$ArN_2^+ \; + \; H_2O \longrightarrow ArOH$$

This reaction is formally analogous to **13-1**, but with a N_2^+ leaving group rather than a halide. Water is usually present whenever diazonium salts are made, but at these temperatures (0–5°C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, for example, boiling with aqueous sulfuric acid or with trifluoroacetic acid containing potassium trifluoroacetate.[702] The reaction can be performed on solutions of any diazonium salts, but hydrogen sulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles Cl^- or NO_3^-. A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields consists of adding Cu_2O to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of $Cu(NO_3)_2$.[703] Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least partly involved when ordinary hydroxy-de-diazoniation is carried out in weakly alkaline aqueous solution.[704] Decomposition of arenediazonium tetrafluoroborates in F_3CSO_2OH gives aryl triflates directly, in high yields.[705]

13-21 Replacement by Sulfur-Containing Groups

Mercapto-de-diazoniation, and so on

$$ArN_2^+ + HS^- \longrightarrow ArSH$$
$$ArN_2^+ + S^{2-} \longrightarrow ArSAr$$
$$ArN_2^+ + RS^- \longrightarrow ArSR$$
$$ArN_2^+ + SCN^- \longrightarrow ArSCN + ArNCS$$

These reactions are convenient methods for incorporating a sulfur-containing group onto an aromatic ring. With Ar'S$^-$, diazosulfides Ar—N=N—S—Ar' are intermediates,[706] which can in some cases be isolated.[707] Thiophenols can be made as shown above, but more often the diazonium ion is treated with EtO–CSS$^-$ or S_2^{2-}, which give the expected products, and these are easily convertible to thiophenols. Aryldiazonium salts are prepared by the reaction of an aniline derivative with an alkyl nitrite (RONO), and when formed in the presence of dimethyl disulfide (MeS–SMe), the product is the thioether, Ar–S–Me.[708] Aryl triflates have been converted to the aryl thiol using NaST(P5) and a palladium catalyst, followed by treatment with tetrabutylammonium fluoride[709] (see also, **14-22**).

OS **II**, 580; **III**, 809 (but see OS **V**, 1050). Also see, OS **II**, 238.

13-22 Replacement by Iodine

Iodo-de-diazoniation

$$ArN_2^+ + I^- \longrightarrow ArI$$

One of the best methods for the introduction of iodine into aromatic rings (see **13-7**) is the reaction of diazonium salts with iodide ions. Analogous reactions with chloride, bromide, and fluoride ions give poorer results, and **14-20** and **13-23** are preferred for the preparation of aryl chlorides, bromides, and fluorides. However, when other diazonium reactions are carried out in the presence of these ions, halides are usually side products. Aniline has also been converted to fluorobenzene by treatment with *t*-BuONO and SiF_4 followed by heating.[710] A related reaction between PhN=N–NC_4H_8 and iodine gave iodobenzene.[711]

The actual attacking species is probably not only I^- if it is I^- at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent)

to iodine, which in a solution containing iodide ions is converted to I_3^-; this is the actual attacking species, at least partly. This was shown by isolation of ArN_2^+ I_3^- salts, which, on standing, gave ArI.[712] From this, it can be inferred that the reason the other halide ions give poor results is not that they are poor nucleophiles but that they are poor reducing agents (compared with iodide). There is also evidence for a free-radical mechanism.[713]

The hydroxyl group of a phenol can be replaced with iodine. The reaction of phenol with a boronic ester and a palladium catalyst, followed by reaction with NaI and chloramine-T converts phenol to iodobenzene.[714]

OS **II**, 351, 355, 604; **V**, 1120.

13-23 The Schiemann Reaction

Fluoro-de-diazoniation (overall transformation)

$$ArN_2^+\ BF_4^- \xrightarrow{\Delta} ArF \quad + \quad N_2 \quad BF_3$$

Heating of diazonium fluoroborates (the *Schiemann* or *Balz–Schiemann reaction*) is by far the best way of introducing fluorine into an aromatic ring.[715] In the most common procedure, the fluoroborate salts are prepared by diazotizing as usual with nitrous acid and HCl and then adding a cold aqueous solution of $NaBF_4$, HBF_4, or NH_4BF_4. A precipitate forms, which is dried, and the salt is heated in the dry state. These salts are unusually stable for diazonium salts, and the reaction is usually successful. In general, any aromatic amine that can be diazotized will form a BF_4^- salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *tert*-butyl nitrite and BF_3–etherate.[716] The reaction has also been carried out on ArN_2^+ PF_6^-, ArN_2^+ SbF_6^-, and ArN_2^+ AsF_6^- salts, in many cases with better yields.[717] Aryl chlorides and bromides are more commonly prepared by the Sandmeyer reaction (**14-20**). In an alternative procedure, aryl fluorides have been prepared by treatment of aryltriazenes Ar–N=N–NR_2 with 70% HF in pyridine.[718]

The mechanism is of the S_N1 type. That aryl cations are intermediates was shown by the following experiments:[719] Aryl diazonium chlorides are known to

arylate other aromatic rings by a free-radical mechanism (see **13-27**). In radical arylation it does not matter whether the other ring contains electron-withdrawing or electron-donating groups; in either case a mixture of isomers is obtained, since the attack is not by a charged species. If an aryl radical were an intermediate in the Schiemann reaction and the reaction were run in the presence of other rings, it should not matter what kinds of groups were on these other rings: Mixtures of biaryls should be obtained in all cases. But if an aryl cation is an intermediate in the Schiemann reaction, compounds containing meta-directing groups, that is, meta directing for *electrophilic* substitutions, should be meta-arylated and those containing ortho–para-directing groups should be ortho– and para arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown[720] that such orientation is observed, demonstrating that the Schiemann reaction has a positively charged intermediate. The attacking species, in at least some instances, is not F^- but BF_4^-.[721]

OS **II**, 188, 295, 299; **V**, 133.

13-24 Conversion of Amines to Azo Compounds

***N*-Arylimino-de-dihydro-bisubstitution**

$$ArNH_2 \quad + \quad Ar'NO \xrightarrow{\text{HOAc}} Ar{-}N{=}N{-}Ar'$$

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).[722] A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds $ArNO_2$ and *N*-acyl aromatic amines Ar'NHAc.[723] The use of phase-transfer catalysis increased the yields.

13-25 Methylation, Vinylation, and Arylation of Diazonium Salts

Methyl-de-diazoniation, and so on

$$ArN_2^+ \quad + \quad Me_4Sn \xrightarrow[\text{MeCN}]{\text{Pd(OAc)}_2} ArMe$$

A methyl group can be introduced into an aromatic ring by treatment of diazonium salts with tetramethyltin and a palladium acetate catalyst.[724] The reaction has been performed with Me, Cl, Br, and NO_2 groups on the ring. A vinylic group can

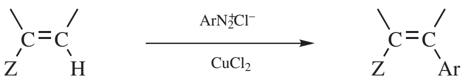
be introduced with $CH_2{=}CHSnBu_3$. When an aryl amine is treated with *tert*-butyl hyponitrite (*t*-BuONO) and allyl bromide, the nitrogen is displaced to the give allyl–aryl compound.[725]

Aryl diazonium salts can be used coupled with alkenes in a Heck-like reaction (**12-15**).[726] Other reactive aryl species also couple with aryldiazonium salts in the presence of a palladium catalyst.[727] A Suzuki type coupling (**13-9**) has also been reported using arylboronic acids, aryldiazonium salts and a palladium catalyst.[728]

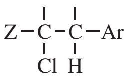
Aryltrifluoroborates (**12-28**) react with aryldiazonium salts in the presence of a palladium catalyst to give the corresponding biaryl.[729] Arylborate esters also reacat using a palladium catlsyt, and the aryl dizaonium unit reacts faster than an aryl halide.[730]

13-26 Arylation of Activated Alkenes by Diazonium Salts: Meerwein Arylation

Arylation or **Aryl-de-hydrogenation**



Alkenes activated by an electron-withdrawing group (Z may be C=C, halogen, C=O, Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a cupric chloride[731] catalyst. This is called the *Meerwein*



arylation reaction.[732] Addition of ArCl to the double bond (to give) is a side reaction (**15-46**). In an improved procedure, an arylamine is treated with an alkyl nitrite (generating ArN_2^+ *in situ*) and a copper(II) halide in the presence of the alkene.[733]

The mechanism is probably of the free-radical type, with AR• (**36**) forming as in **14-20**, and then halogen transfer to give **37** or elimination to give **38**.[734]

The radical **36** can react with cupric chloride by two pathways, one of which leads to addition and the other to substitution. Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl. Note that radical reactions are presented in Chapter 14, but the coupling of an alkene with an aromatic compound containing a leaving group prompted its placement here. Note also the similarity to the Heck reaction in **13-10**.

A variation of this reaction uses a palladium–copper catalyst on Montmorillonite clay. When aniline reacted with methyl acrylate in acetic acid and the Pd–Cu–Montmorillonite K10, $PhCH{=}CHCO_2Me$ was obtained.[735]

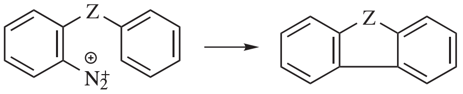
OS **IV**, 15.

13-27 Arylation of Aromatic Compounds by Diazonium Salts

Arylation or **Aryl-de-hydrogenation**

$$ArH + Ar'N_2^+ X^- \xrightarrow{OH^-} Ar{-}Ar'$$

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg* or *Gomberg–Bachmann reaction*,[736] it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually <40%) because of the many side reactions undergone by diazonium salts, though higher yields have been obtained under phase-transfer conditions.[737] The conditions of the Meerwein reaction (**13-26**), treatment of the solution with a copper-ion catalyst, have also been used, as has the addition of sodium nitrite in Me_2SO (to benzene diazonium fluoroborate in DMSO).[738]



39

[737]Beadle, J.R.; Korzeniowski, S.H.; Rosenberg, D.E.; Garcia-Slanga, B.J.; Gokel, G.W. *J. Org. Chem.* ***1984***, *49*, 1594.

[738]Kamigata, N.; Kurihara, T.; Minato, H.; Kobayashi, M. *Bull. Chem. Soc. Jpn.* ***1971***, *44*, 3152.

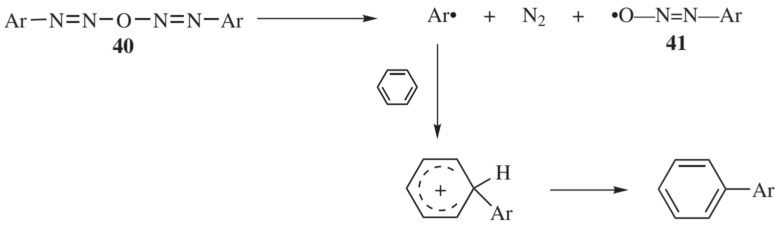
When the Gomberg–Bachmann reaction is performed intramolecularly as in the formation of **39**, either by the alkaline solution or by the copper-ion procedure, it is called the *Pschorr ring closure*[739] and yields are usually somewhat higher. Still higher yields have been obtained by carrying out the Pschorr reaction electrochemically.[740] The Pschorr reaction has been carried out for Z = CH=CH, CH_2CH_2, NH, C=O, CH_2, and quite a few others. A rapid and convenient way to carry out the Pschorr synthesis is to diazotize the amine substrate with isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.[741]

Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are *N*-nitroso amides [ArN(NO)COR], triazenes,[742] and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.[743]

In each case, the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution, diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (see p. 856). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals (Ar• and Z•). Note that radical reactions are presented in Chapter 14, but the coupling of an aromatic ring with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the Suzuki reaction in **13-12**.

$$\text{Ar—N=N—Z} \longrightarrow \text{Ar}\bullet + \text{N}\equiv\text{N} + \text{Z}\bullet$$

Under Gomberg–Bachmann conditions, the species that cleaves is the anhydride, **40**.[744]



42 **43**

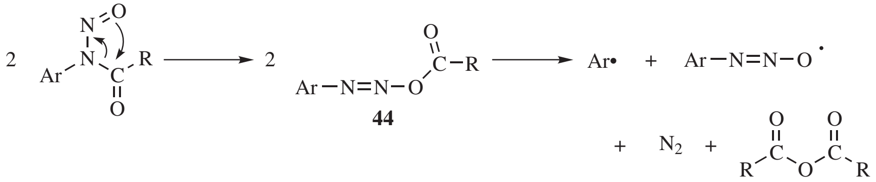
[741]Chauncy, B.; Gellert, E. *Aust. J. Chem.* ***1969***, *22*, 993. See also, Duclos, Jr., R.I.; Tung, J.S.; Rappoport, H. *J. Org. Chem.* ***1984***, *49*, 5243.

[742]See, for example, Patrick, T.B.; Willaredt, R.P.; DeGonia, D.J. *J. Org. Chem.* ***1985***, *50*, 2232; Butler, R.N.; O'Shea, P.D.; Shelly, D.P. *J. Chem. Soc. Perkin Trans. 1*, ***1987***, 1039.

[743]Cadogan, J.I.G. *J. Chem. Soc.* ***1962***, 4257; Fillipi, G.; Vernin, G.; Dou, H.J.; Metzger, J.; Perkins, M.J. *Bull. Soc. Chim. Fr.* ***1974***, 1075.

[744]Rüchardt, C.; Merz, E. *Tetrahedron Lett.* ***1964***, 2431; Eliel, E.L.; Saha, J.G.; Meyerson, S. *J. Org. Chem.* ***1965***, *30*, 2451.

The aryl radical thus formed attacks the substrate to give the intermediate **42** (see p. 940), from which the radical **41** abstracts hydrogen to give the product, **43**. *N*-Nitroso amides probably rearrange to *N*-acyloxy compounds (**44**), which cleave to give aryl radicals.[745] There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.[746]



44

The Pschorr reaction can take place by two different mechanisms, depending on conditions: (*1*) attack by an aryl radical (as in the Gomberg–Bachmann reaction) or (*2*) attack by an aryl cation (similar to the S_N1 mechanism discussed on p. 857).[747] Under certain conditions the ordinary Gomberg–Bachmann reaction can also involve attack by aryl cations.[748]

OS **I**, 113; **IV**, 718.

13-28 Aryl Dimerization With Diazonium Salts

De-diazonio-coupling; Arylazo-de-diazonio-substitution

$$2\,ArN_2^+ \xrightarrow[\text{or}\quad Cu + H^+]{Cu^+} Ar{-}Ar + 2\,N_2 \quad \text{or} \quad Ar{-}N{=}N{-}Ar + N_2$$

When diazonium salts are treated with cuprous ion (or with copper and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from **13-27** (and from **19-14**) in that *both* aryl groups in the product originate from ArN_2^+, that is, hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.[749]

OS **I**, 222; **IV**, 872. Also see, OS **IV**, 273.

13-29 Replacement of Nitro

Alkyl-de-nitration, Hydroxy and alkoxy-de-nitration, Halo-de-nitration

$$Ar\text{-}NO_2 \longrightarrow Ar\text{-}R$$

In some cases, the nitrogen group of an aromatic nitro compound can be replaced with an alkyl group. The reaction of 1,4-dinitrobenzene with potassium *tert*-butoxide in the presence of BEt_3, for example, gave 4-ethylnitrobenzene.[750]

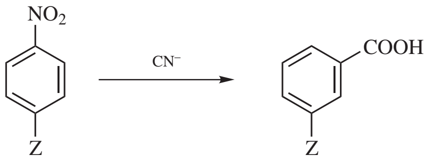
Other nucleophiles can replace a nitrogen-containing group. The reaction of hydroxide with Ar–Y, where Y = nitro,[751] azide, NR_3^+, and so on gives the corresponding phenol. This latter reaction works with alkoxide nucleophiles to give the corresponding aryl ether. The nitro can be replaced with chloro by use of NH_4Cl, PCl_5, $SOCl_2$, HCl, Cl_2, or CCl_4. Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with fluoride ion.[752]

The reaction of vinyl nitro compounds ($C{=}C\text{–}NO_2$) and aryl iodide to give the styrene compound (C=C–Ar) was reported using BEt_3 and exposure to air.[753]

REARRANGEMENTS

13-30 The von Richter Rearrangement

Hydro-de-nitro-*cine*-substitution



When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with cine substitution (p. 860), always ortho to the displaced group, never meta or para. The scope of this reaction, called the *von Richter rearrangement*, is variable.[754] As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in ortho and para positions, but yields are low, usually $<20\%$ and never $>50\%$.

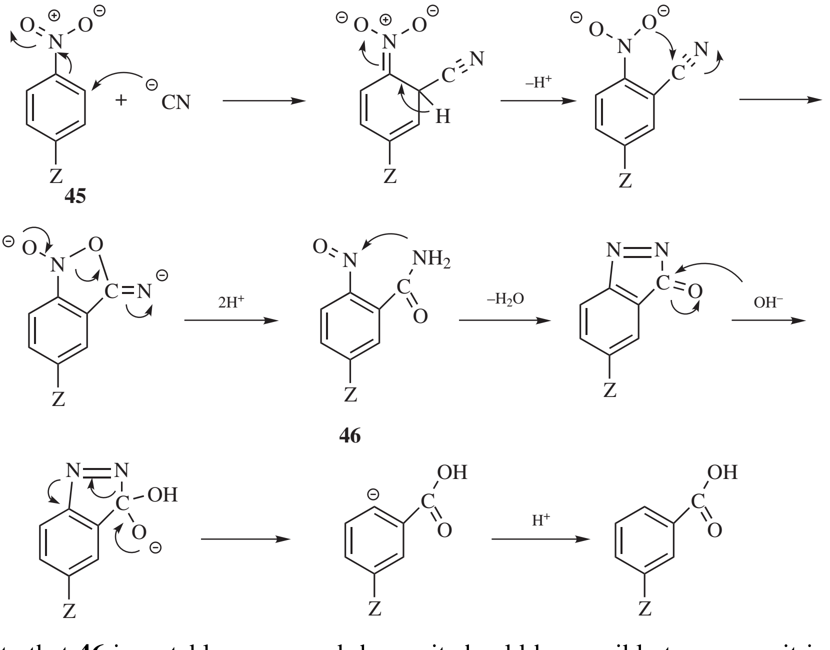
[754]For a review, see Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 326–335.

At one time it was believed that a nitrile, ArCN, was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (**16-4**). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut demonstrated[755] that α-naphthyl cyanide is *not* hydrolyzable to α-naphthoic acid under conditions at which β-nitronaphthalene undergoes the von Richter rearrangement to give α-naphthoic acid. This proved that the nitrile cannot be an intermediate. It was subsequently demonstrated that N_2 is a major product of the reaction.[756] It had previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that NO_2^- is not a major product. The discovery of nitrogen indicated that a nitrogen–nitrogen bond must be formed during the course of the reaction. A mechanism in accord with all the facts was proposed by Rosenblum:[756]



45

46

Note that **46** is a stable compound; hence it should be possible to prepare it independently and to subject it to the conditions of the von Richter rearrangement. This was done and the correct products are obtained.[757] Further evidence is that when **45** (Z = Cl or Br) was treated with cyanide in $H_2{}^{18}O$, half the oxygen in the product was labeled, showing that one of the oxygens of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.[758]

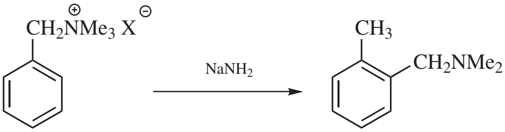
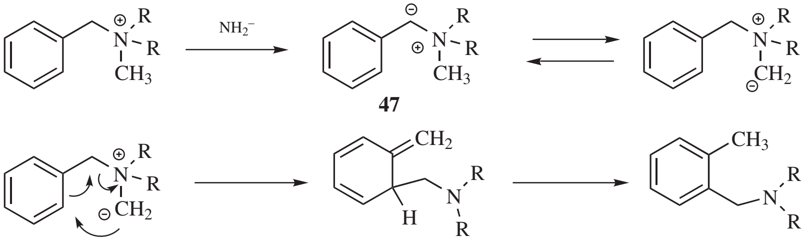
13-31 The Sommelet–Hauser Rearrangement



Benzylic quaternary ammonium salts, when treated with alkali-metal amides, undergo a rearrangement called the *Sommelet–Hauser rearrangement.*[759] Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an ortho position is blocked.[760]

The rearrangement occurs with high yields and can be performed with various groups present in the ring.[761] The reaction is most often carried out with three methyl groups on the nitrogen, but other groups can also be used, though if a β-hydrogen is present, Hofmann elimination (**17-7**) often competes. The *Stevens rearrangement* (**18-21**) is also a competing process.[762] When both rearrangements are possible, the Stevens is favored at high temperatures and the Sommelet–Hauser at low temperatures.[763] The mechanism is



The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylid **47**. However, **48**, which is present in smaller amount, is the species

[759]For reviews, see Pine, S.H. *Org. React.*, ***1970***, *18*, 403; Lepley, A.R.; Giumanini, A.G. *Mech. Mol. Migr.* ***1971***, *3*, 297; Wittig, G. *Bull. Soc. Chim. that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3] sigmatropic rearrangement (see **18-35**). Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.[764] If the second mechanism were true, **49** should give **50**, but the first mechanism predicts the formation of **51**, which is what was actually obtained.[765]

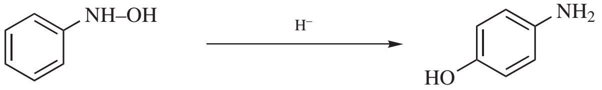
The mechanism as we have pictured it can lead only to an ortho product. However, a small amount of para product has been obtained in some cases.[766] A mechanism[767] in which there is a dissociation of the ArC—N bond (similar to the ion-pair mechanism of the Stevens rearrangement, p. 1622) has been invoked to explain the para products that are observed.

Sulfur ylids containing a benzylic group (analogous to **48**) undergo an analogous rearrangement.[768]

OS **IV**, 585.

13-32 Rearrangement of Aryl Hydroxylamines

1/*C*-Hydro-5/*N*-hydroxy-interchange



Aryl hydroxylamines treated with acids rearrange to aminophenols.[769] Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to

[764]For other evidence for the mechanism given, see Hauser, C.R.; Van Eenam, D.N. *J. Am. Chem. Soc.* ***1957***, *79*, 5512; Jones, F.N.; Hauser, C.R. *J. Org. [769]For a review, see Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 182–190.

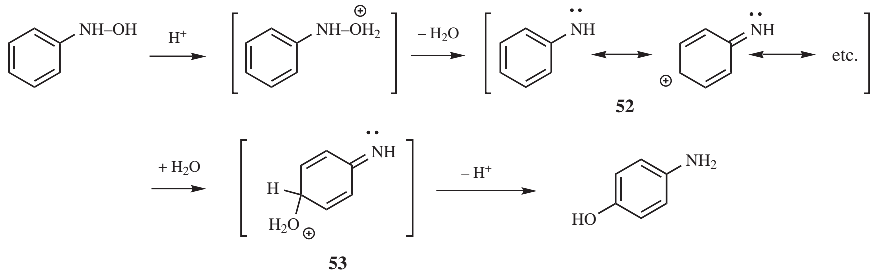
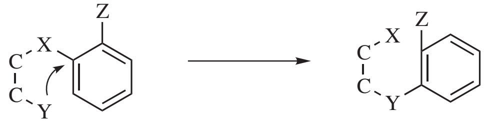
11-28–11-32, the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:



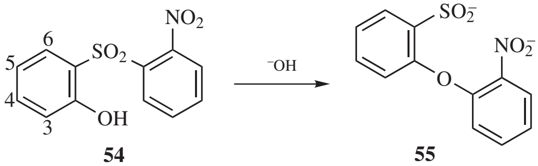
Among the evidence[770] for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles, for example, *p*-ethoxyaniline when ethanol is present, and that when the para position is blocked, compounds similar to **53** are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion **52** was trapped, and its lifetime in solution was measured.[771] The reaction of **52** with water was found to be diffusion controlled.[288]

OS **IV**, 148.

13-33 The Smiles Rearrangement



The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern given above.[772] A specific example is the reaction of **54** with hydroxide to give **55**.



Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given, SO_2Ar is the leaving group and ArO^- the nucleophile, and the nitro group serves to activate its ortho position. Halogens also serve as activating

[770]For additional evidence, see Sone, T.; Hamamoto, K.; Seiji, Y.; Shinkai, S.; Manabe, O. *J. Chem. Soc. Perkin Trans. 2* ***1981***, 1596; Kohnstam, G.; Petch, W.A.; Williams, D.L.H. *J. Chem. [772]For reviews, see Truce, W.E.; Kreider, E.M.; Brand, W.W. *Org. React.*, ***1971***, *18*, 99; Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, ***1967***, pp. 307–316; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand-Reinhold, Princeton, NJ, ***1973***, pp. 120–126.

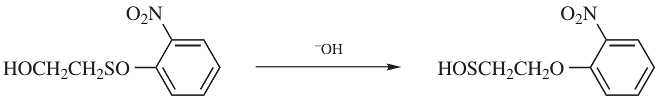
groups.[773] The ring at which the substitution takes place is nearly always activated, usually by ortho or para nitro groups. Here X is usually S, SO, SO_2,[774] O, or COO, and Y is usually the conjugate base of OH, NH_2, NHR, or SH. The reaction has even been carried out with $Y = CH_2^-$ (phenyllithium was the base here).[775]

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **54** caused the rate to be ~10^5 times faster than when the same groups were in the 4 position,[776] though electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation the molecule can adopt to suit the bulk of the 6-substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the Smiles rearrangement is usually carried out on compounds containing two rings, this need not be the case, as in the formation of **56**.[777]



56

In this case, the sulfenic acid (**56**) is unstable[778] and the actual products isolated were the corresponding sulfinic acid (RSO_2H) and disulfide (R_2S_2).

[778]For a stable sulfenic acid, see Nakamura, N. *J. Am. Chem. Soc.* ***1983***, *105*, 7172.

In the Smiles rearrangement, the nucleophile Y is most often the conjugate base of SH, SO_2NHR, SO_2NH_2, NH_2, NHR, OH, OR. There are few examples where Y is a carbanion, and the most common example is probably the *Truce–Smiles rearrangement*, where L—YH is an *o*-tolyl group.[779] The prototypical Truce–Smiles rearrangement requires use of a strong base to form the benzylic carbanion that undergoes the rearrangement. When sulfone **57** was treated with butyllithium, for example, deprotonation led to the benzylic lithium compound **58**. Truce–Smiles rearrangement led to **59**, and hydrolysis gave the sulfinic acid, **60**.[779] Truce–Smiles rearrangements with stabilized benzylic carbanions are known,[780] and rearrangements of carbanions in general fall under this category.[781] Relatively few examples have been reported, however.[782] Truce–Smiles rearrangements of sulfones that proceed through a six-membered transition state have been reported.[783] In another example, displacement of an activated aryl fluoride with *o*-hydroxyacetophenone gave a product that was *C*-arylated adjacent to the ketone.[784]

CHAPTER 14

Substitution Reactions: Free Radicals

MECHANISMS

Free-Radical Mechanisms in General[1]

A free-radical process consists of at least two steps. The first step involves the *formation* of free radicals, usually by homolytic cleavage of bond, that is, a cleavage in which each fragment retains one electron:

$$\text{A—B} \longrightarrow \text{A}\bullet + \text{B}\bullet$$

This is called an *initiation* step. It may happen spontaneously or may be induced by heat[2] or light (see the discussion on p. 279), depending on the type of bond.[3] Peroxides, including hydrogen peroxide, dialkyl, diacyl, and alkyl acyl peroxides, and peroxyacids are the most common source of free radicals induced spontaneously or by heat, but other organic compounds with low-energy bonds, such as azo compounds, are also used. Molecules that are cleaved by light are most often chlorine, bromine, and various ketones (see Chapter 7). Radicals can also be formed

in another way, by a one-electron transfer (loss or gain), for example, $A^+ + e^- \rightarrow A\bullet$. One-electron transfers usually involve inorganic ions or electrochemical processes.

Dialkyl peroxides (ROOR) or alkyl hydroperoxides (ROOH) decompose to hydroxy radicals (HO•) or alkoxy radicals (RO•) when heated.[4] Cumene hydroperoxide ($PhCMe_2OOH$), bi-*tert*-butylperoxide ($Me_3COOCMe_3$),[5] and benzoyl peroxide [$(PhCO)O_2$] undergo homolytic cleavage at temperatures compatible with many organic reactions, allowing some control of the reaction, and they are reasonably soluble in organic solvents. In general, when a peroxide decomposes, the oxygen radical remains in a "cage" for $\sim 10^{-11}$ s before diffusing away. The radical can recombine (dimerize), or react with other molecules. Azo compounds, characterized by a —N=N— bond, are free-radical precursors that liberate nitrogen gas (N≡N) upon decomposition. azobis(isobutyronitrile) (AIBN, **1**) is a well-known example, which decomposes to give nitrogen and the cyano stabilized radical, **2**.[6] Homolytic dissociation of symmetrical diazo compounds may be stepwise.[7] A derivative has been developed that decomposes to initiate radical reactions at room temperature, 2,2′-azobis(2,4-dimethyl-4-methoxyvaleronitrile), **3**.[8] Water soluble azo compounds are known, and can be used as radical initiators.[9] Other sources of useful radicals are available. Alkyl hypochlorites (R—O—Cl) generate chlorine radicals (Cl•) and alkoxy radicals (RO•) when heated.[10] Heating *N*-alkoxydithiocarbamates is another useful source of alkoxy radicals, RO•.[11]

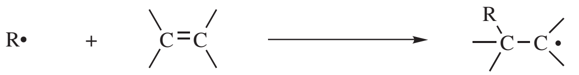
[11]Kim, S.; Lim, C.J.; Song, S.-E.; Kang, H.-Y. *Synlett* ***2001***, 688.

Note that aldehydes can also be a source of acyl radicals (•C=O) via reaction with transition metal salts such as Mn(III) acetate or Fe(II) compounds.[12] Another useful variation employs imidoyl radicals as synthons for unstable aryl radicals.[13]

The second step involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:[14]

$$A\bullet + B\bullet \longrightarrow A{-}B$$

This type of step is called *termination*, and it ends the reaction as far as these particular radicals are concerned.[15] However, it is not often that termination follows *directly* upon initiation. The reason is that most radicals are very reactive and will react with the first available species with which they come in contact. In the usual situation, in which the concentration of radicals is low, this is much more likely to be a molecule than another radical. When a radical (which has an odd number of electrons) reacts with a molecule (which has an even number), the total number of electrons in the products must be odd. The product in a particular step of this kind may be one particle, as in the addition of a radical to a π-bond, which in this case is



4

another free radical, **4**; or abstraction of an atom such as hydrogen to give two particles, R—H and the new radical R′•.

$$R\bullet + R'H \longrightarrow RH + R'\bullet$$

In this latter case, one particle must be a neutral molecule and one a free radical. In both of these examples, a *new radical is generated.* This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until two radicals do meet each other and terminate the sequence. The process just described is called a *chain reaction*,[16] and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a

[12]Davies, D.I.; Parrott, M.J. *Free Radicals in Organic Synthesis* Springer–Verlag, Berlin, ***1978***, p. 69; Sosnovsky, G. *Free Radical Reactions in Preparative Organic Chemistry*, MacMillan, New York, ***1964***; Vinogradov, M.G.; Nikishin, G.I. *Usp. Org. Chem, USSR* ***1972***, *8*, 539 (Engl, p. 544).

[13]Fujiwara, S.-i.; Matsuya, T.; Maeda, H.; Shin-ike, T.; Kambe, N.; Sonoda, N. *J. Org. Chem.* ***2001***, *66*, 2183.

[14]For a review of the stereochemistry of this type of combination reaction, see Porter, N.A.; Krebs, P.J. *Top. Stereochem.* ***1988***, *18*, 97.

[15]Another type of termination is disproportionation (see p. 280).

[16]For a discussion of radical chain reactions from a synthetic point of view, see Walling, C. *Tetrahedron* ***1985***, *41*, 3887.

molecule at all. These are (*1*) cleavage of a radical into, necessarily, a radical and a molecule and (*2*) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive, for example, alkyl radicals, chains are long, since reactions occur with many molecules; but with radicals of low reactivity, for example, aryl radicals, the radical may be unable to react with anything until it meets another radical, so that chains are short, or the reaction may be a nonchain process. In any particular chain process, there is usually a wide variety of propagation and termination steps. Because of this, these reactions lead to many products and are often difficult to treat kinetically.[17]

$$\text{R—CH}_2\bullet + n\text{-Bu}_3\text{Sn—H} \longrightarrow \text{R—CH}_2\text{—H} + n\text{-Bu}_3\text{Sn}\bullet$$

$$n\text{-Bu}_3\text{Sn}\bullet + n\text{-Bu}_3\text{Sn}\bullet \longrightarrow n\text{-Bu}_3\text{Sn—Sn}n\text{-Bu}_3$$

A useful variation of propagation and termination combines the two processes. When a carbon radical (R•) is generated in the presence of tributyltin hydride (n-Bu_3SnH), a hydrogen atom is transferred to the radical to give R—H and a new radical, n-Bu_3Sn•. The tin radical reacts with a second tin radical to give n-Bu_3 Sn—Sn—n-Bu_3. The net result is that the carbon radical is reduced to give the desired product and the tin dimer can be removed from the reaction. Tin hydride transfers a hydrogen atom in a chain propagation sequence that produces a new radical, but terminates the carbon radical sequence. Dimerization of the tin radical then terminates that radical process. Silanes, such as triethylsilane (Et_3SiH), has also been used as an effective radical reducing agent.[18] The rate constants for the reaction of both tributytin hydride and $(Me_3Si)_3Si$—H with acyl radical has been measured and the silane quenches the radical faster than the tin hydride.[19] bis(Tri-n-butylstannyl)benzopinacolate has also been used as a thermal source of n-Bu_3Sn•, used to mediate radical reactions.[20]

The following are some general characteristics of free-radical reactions:[21]

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, though solvation of free radicals in solution does cause some differences.[22]
2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.

[17]For a discussion of the kinetic aspects of radical chain reactions, see Huyser, E.S. *Free-Radical Chain Reactions*, Wiley, NY, ***1970***, pp. 39–65.

3. They are initiated or accelerated by typical free-radical sources, such as the peroxides, referred to, or by light. In the latter case, the concept of quantum yield applies (p. 349). Quantum yields can be quite high, for example, 1000, if each quantum generates a long chain, or low, in the case of nonchain processes.
4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals, for example, nitric oxide, molecular oxygen, or benzoquinone. These substances are called *inhibitors*.[23]

This chapter discusses free-radical substitution reactions. Free-radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. Fragmentation reactions are covered, in part, in Chapter 17. In addition, many of the oxidation–reduction reactions considered in Chapter 19 involve free-radical mechanisms. Several important types of free-radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book. Among these are polymerizations and high-temperature pyrolyses.

Free-Radical Substitution Mechanisms[24]

In a free-radical substitution reaction

$$\text{R—X} \longrightarrow \text{R—Y}$$

there must first be a cleavage of the substrate RX so that R• radicals are produced. This can happen by a spontaneous cleavage

$$\text{R—X} \longrightarrow \text{R•} + \text{X•}$$

or it can be caused by light or heat, or, more often, there is no actual cleavage, but R• is produced by an *abstraction* of another atom, X but the radical W•.

$$\text{R—X} + \text{W•} \longrightarrow \text{R•} + \text{W—X}$$

The radical W• is produced by adding a compound, such as a peroxide, that spontaneously forms free radicals. Such a compound is called an *initiator* (see above). Once R• is formed, it can go to product in two ways, by another atom abstraction, such as the reaction with A—B to form R—A and a new radical B•.

$$\text{R•} + \text{A—B} \longrightarrow \text{R—A} + \text{B•}$$

Another reaction is coupling with another radical to form the neutral product R—Y.

$$\text{R•} + \text{Y•} \longrightarrow \text{R—Y}$$

[23]For a review of the action of inhibitors, see Denisov, E.T.; Khudyakov, I.V. *Chem. Rev.* ***1987***, *87*, 1313.
[24]For a review, see Poutsma, M.L., in Kochi, J.K. *Free Radicals*, Vol. 2, Wiley, NY, ***1973***, pp. 113–158.

In a reaction with a moderately long chain, much more of the product will be produced by abstraction (4) than by coupling (5). Cleavage steps like (2) have been called S_H1 (H for homolytic), and abstraction steps like (3) and (4) have been called S_H2; reactions can be classified as S_H1 or SH_2 on the basis of whether RX is converted to R by (2) or (3).[25] Most chain substitution mechanisms follow the pattern (3), (4), (3), (4)••• Chains are long and reactions go well where both (3) and (4) are energetically favored (no worse that slightly endothermic (see pp. 944, 959). The IUPAC designation of a chain reaction that follows the pattern (3),(4)••• is $A_rD_R + A_RD_r$ (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. For example, consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that in the transition state there is a separation of charge, with a partial negative charge on the halogen and a partial positive charge on the carbon:

$$\overset{\delta+}{PhCH_2}\cdots\cdots\cdots H \cdots\cdots\cdots \overset{\delta-}{Br}$$

Evidence for the polar character of the transition state is that electron-withdrawing groups in the para position of toluene (which would destabilize a positive charge) decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.[26] However, substituents have a smaller effect here ($\rho \sim -1.4$) than they do in reactions where a completely ionic intermediate is involved, for example, the S_N1 mechanism (see p. 487). Other evidence for polar transition states in radical abstraction reactions is mentioned on p. 948. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen abstraction from ring-substituted toluenes by the methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.[27] Those radicals (e.g., Br•) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

When the reaction step R—X → R• takes place at a chiral carbon, racemization is almost always observed because free radicals do not retain configuration. Exceptions to this rule are found at cyclopropyl substrates, where both inversion[28] and retention[29] of configuration have been reported, and in the reactions mentioned on p. 942. Enantioselective radical processes have been reviewed.[30]

Mechanisms at an Aromatic Substrate[31]

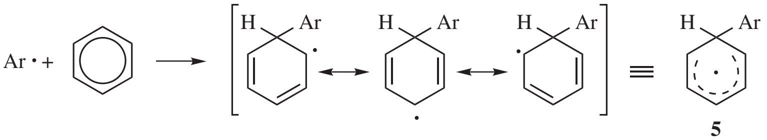
When R in reaction (1) is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes, such as the following (see **13-27**, **14-17**, and **14-18**):

$$\text{Ar}\bullet \quad + \quad \text{ArH} \longrightarrow \text{Ar—Ar}$$

which occur in solution, the coupling of two rings cannot be explained on the basis of a simple abstraction

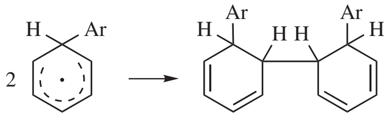
$$\text{Ar}\bullet \quad + \quad \text{ArH} \longrightarrow \text{Ar—Ar} \quad + \quad \text{H}\bullet$$

since, as discussed on p. 944, abstraction of an entire group, such as phenyl, by a free radical is very unlikely. The products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. In the first step, the radical attacks the ring in much the same way as would an electrophile or a nucleophile:

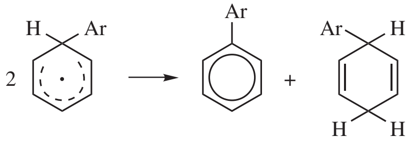


5

The intermediate radical **5** is relatively stable because of the resonance. The reaction can terminate in three ways: by simple coupling to give **6**, by disproportionation to give **7**,



6



7

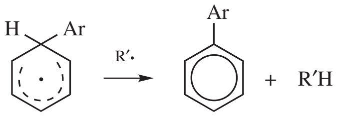
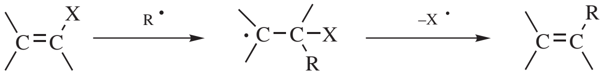
or, if a species (R′•) is present that abstracts hydrogen, by abstraction to give **8**.[32]



8

Coupling product **6** is a partially hydrogenated quaterphenyl. Of course, the coupling need not be ortho–ortho, and other isomers can also be formed. Among the evidence for steps (9) and (10) was isolation of compounds of types **6** and **7**,[33] though normally under the reaction conditions dihydrobiphenyls like **7** are oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **5** by CIDNP[34] and the absence of isotope effects, which would be expected if the rate-determining step were (7), which involves cleavage of the Ar—H bond. In the mechanism just given, the rate-determining step (8) does not involve loss of hydrogen. The reaction between aromatic rings and the HO• radical takes place by the same mechanism. Intramolecular hydrogen-transfer reactions of aryl radicals are known.[35] A similar mechanism has been shown for substitution at some vinylic[36] and acetylenic substrates, giving the substituted alkene **9**.[37] The kinetics of radical heterolysis reactions that form alkene radical cations has been studied.[38]



9

This is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (p. 477).

There are a number of transition-metal mediated coupling reaction of aromatic substrates that probably proceed by radical coupling. It is also likely that many of these reactions do not proceed by free radicals, but rather by metal-mediated radicals or by ligand transfer on the metal. Reactions in these categories were presented

[32]Compound **5** can also be oxidized to the arene ArPh by atmospheric O_2. For a discussion of the mechanism of this oxidation, see Narita, N.; Tezuka, T. *J. Am. Chem. Soc.* ***1982***, *104*, 7316.

[36]The reaction of vinyl chloride with Cl^- favors the σ-route (nucleophilic attack at the σ-bond) over the π-route (nucleophilic attack at the π-bond), but vinyl chloride is not an experimentally viable substrate and cannot be considered as representative for the vinyl S_N2 reaction. The π-route is anticipated in substituted vinylic halide reactions, where electron-withdrawing groups are attached to the vinylic carbon. See Bach, R. D.; Baboul, A. G.; Schlegel, H. B. *J. Am. Chem. Soc*, ***2001***, *123*, 5787.

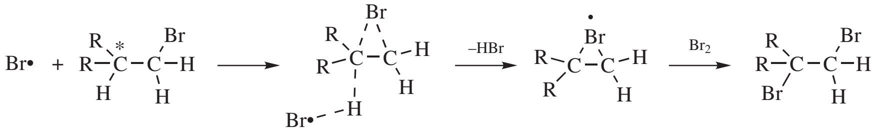
in Chapter 13 for convenient correlation with other displacement reactions of aryl halides, aryl diazonium salts, and so on.

Neighboring-Group Assistance in Free-Radical Reactions

In a few cases, it has been shown that cleavage steps (2) and abstraction steps (3) have been accelerated by the presence of neighboring groups. Photolytic halogenation (**14-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of alkyl bromides gave 84–94% substitution at the carbon adjacent to the bromine already in the molecule.[39] This result is especially surprising because, as we will see (p. 947), positions close to a polar group, such as bromine, should actually be *deactivated* by the electron-withdrawing field effect of the bromine. The unusual regioselectivity is explained by a mechanism in which abstraction (3) is assisted by a neighboring bromine atom, as in **10**.[40]



10 **11**

In the normal mechanism, Br• abstracts a hydrogen from RH, leaving R•. When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **11**).[41] In the final step (very similar to R• + Br_2 → RBr + Br•), the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked *) should be retained. This has been shown to be the case: optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.[40] Furthermore, when this reaction was carried out in the presence of DBr, the "recovered" 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.[42] This is just what would be predicted if some of the **11** present abstracted D from DBr. There is evidence that Cl can form bridged radicals,[43]

though ESR spectra show that the bridging is not necessarily symmetrical.[44] Still more evidence for bridging by Br has been found in isotope effect and other studies.[45] However, evidence from CIDNP shows that the methylene protons of the β-bromoethyl radical are not equivalent, at least while the radical is present in the radical pair [PhCOO••CH_2CH_2Br] within a solvent cage.[46] This evidence indicates that under these conditions $BrCH_2CH_2$• is not a symmetrically bridged radical, but it could be unsymmetrically bridged. A bridged intermediate has also been invoked, when a bromo group is in the proper position, in the Hunsdiecker reaction[47] (**14-30**), and in abstraction of iodine atoms by the phenyl radical.[48] Participation by other neighboring groups (e.g. SR, SiR_3, SnR_3) has also been reported.[49]

REACTIVITY

Reactivity for Aliphatic Substrates[50]

In a chain reaction, the step that determines what the product will be is most often an abstraction step. What is abstracted by a free radical is almost never a tetra-[51] or tervalent atom[52] (except in strained systems, see p. 1027)[53] and seldom a divalent one.[54] Nearly always it is univalent, and so, for organic compounds, it is hydrogen or halogen. For example, a reaction between a chlorine atom and ethane gives an

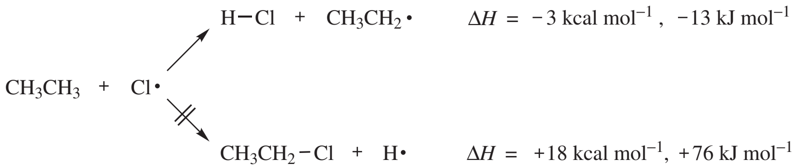
[53]For an example of an abstraction occurring to a small extent at an unstrained carbon atom, see Jackson, R.A.; Townson, M. *J. Chem. Soc. Perkin Trans. 2* ***1980***, 1452. See also, Johnson, M.D. *Acc. Chem. Res.* ***1983***, *16*, 343.

[54]For a monograph on abstractions of divalent and higher valent atoms, see Ingold, K.U.; Roberts, B.P. *Free-Radical Substitution Reactions*, Wiley, NY, ***1971***.

ethyl radical, not a hydrogen atom:



The principal reason for this is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Another reason is that in many cases abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a C_2H_5—H bond is broken ($D = 100$ kcal mol^{-1}, 419 kJ mol^{-1}, from Table 5.3) whichever pathway is taken, but in the former case an H—Cl bond is formed ($D = 103$ kcal mol^{-1}, 432 kJ mol^{-1}) while in the latter case it is a C_2H_5—Cl bond ($D = 82$ kcal mol^{-1}, 343 kJ mol^{-1}). Thus the first reaction is favored because it is exothermic by 3 kcal mol^{-1} (100–103) [13 kJ mol^{-1} (419–432)], while the latter is endothermic by 18 kcal mol^{-1} (100–82) [76 kJ mol^{-1} (419–343)].[55] However, the steric reason is clearly more important, because even in cases where ΔH is not very different for the two possibilities, the univalent atom is chosen.[56] *Ab initio* studies have probed the transition structures for radical hydrogen abstractions.[57]

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.[58] In these reactions, every hydrogen in the substrate is potentially replaceable and mixtures are usually obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. *Ab initio* studies have studied the factors controlling hydrogen abstraction by radicals.[59] For hydrogen abstraction by the *tert*-butoxy radical (*t*-Bu—O•) the factors that influence rate in their order of importance are structure of the radical > substituent effects[60] > solvent effects.[61] We discuss the position of attack under several headings:[62]

[55]The parameter ΔH for a free-radical abstraction reaction can be regarded simply as the difference in D values for the bond being broken and the one formed.

TABLE 14.1. Relative Susceptibility to Attack by Cl• of Primary, Secondary, and Tertiary Positions at 100 and 600°C in the Gas Phase[63]

Temperature, °C	Primary	Secondary	Tertiary
100	1	4.3	7.0
600	1	2.1	2.6

1. *Alkanes*. The tertiary hydrogens of an alkane are the ones preferentially abstracted by almost any radical, with secondary hydrogens being next preferred. This is in the same order as *D* values for these types of C—H bonds (Table 5.3). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. Table 14.1 shows[63] that at high temperatures selectivity decreases, as might be expected.[64] An example of the effect of radical selectivity may be noted in a comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern. For example, in the photochemical chlorination of isopentane in H_2SO_4 with *N*-chloro-di-*tert*-butylamine and *N*-chloro-*tert*-butyl-*tert*-pentylamine, the primary hydrogens are abstracted 1.7 times *faster* than the tertiary hydrogen.[65] In this case, the attacking radicals (the radical ions $R_2NH\bullet^+$, see p. 958) are bulky enough for steric hindrance to become a major factor.

12

Cyclopropylcarbinyl radicals (**12**) are alkyl radicals, but they undergo rapid ring opening to give butenyl radicals.[66] The rate constant for this process has been measured by picosecond radical kinetic techniques to be in the range of $10^7\,M^{-1}\,s^{-1}$ for the parent[67] to $10^{10}\,M^{-1}\,s^{-1}$ for substituted derivatives.[68] Cyclobutylcarbinyl radicals undergo the cyclobutylcarbinyl to

4-pentenyl radical process,[69] but examples are generally limited to the parent system and phenyl-substituted derivatives.[70] Cyclization of the 4-pentenyl radical is usually limited to systems where a stabilized radical can be formed.[71] The effect of substituents has been studied.[72] This process has been observed in bicyclo[4.1.0]heptan-4-ones.[73]

The rate of the ring-opening reaction of **5**,[74] and other substrates have been determined using an indirect method for the calibration[75] of fast radical reactions, applicable for radicals with lifetimes as short as 1 ps.[76] This 'radical clock'[77] method is based on the use of Barton's use of pyridine-2-thione-*N*-oxycarbonyl esters as radical precursors and radical trapping by the highly reactive thiophenol and benzeneselenol.[78] A number of radical clock substrates are known.[79] Other radical clock processes include: racemization of radicals with chiral conformations,[80] one-carbon ring expansion in cyclopentanones,[81] norcarane and spiro[2,5]octane,[82] α- and β-thujone radical rearrangements,[83] and cyclopropylcarbinyl radicals or alkoxycarbonyl radicals containing stabilizing substituents.[84]

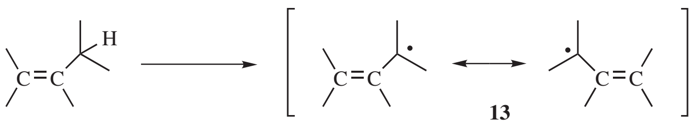
2. *Alkenes*. When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution. However, for other radicals (and even for chlorine or bromine atoms when they do abstract a hydrogen) the position of attack is perfectly clear. Vinylic hydrogens are practically never abstracted, and allylic hydrogens are greatly preferred to other positions of the molecule. Allylic hydrogen abstraction from a cyclic alkenes is usually faster than abstraction from an acyclic alkene.[85] This is generally attributed[86] to resonance stabilization of the allylic radical, **13**. As might be expected, allylic rearrangements (see p. 469) are common in these cases.[87]



13

3. *Alkyl Side Chains of Aromatic Rings*. The preferential position of attack on a side chain is usually the one to the ring. Both for active radicals, such as chlorine and phenyl, and for more selective ones, such as bromine, such attack is faster than that at a primary carbon, but for the active radicals benzylic attack is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogens even more, as would be expected from the resonance involved. These statements can be illustrated by the following abstraction ratios:[88]

	Me–H	$MeCH_2$–H	Me_2CH–H	Me_3C–H	$PhCH_2$–H	Ph_2CH–H	Ph_3C–H
Br	0.0007	1	220	19,400	64,000	1.1×10^6	6.4×10^6
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogens are seldom abstracted if there are aliphatic ones to compete (note from Table 5.3, that *D* for Ph–H is higher than that for any alkyl H bond). Several σ• scales (similar to the σ, σ^+, and σ^- scales discussed in Chapter 9) have been developed for benzylic radicals.[89]

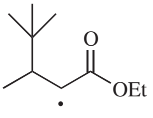
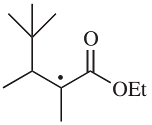
4. *Compounds Containing Electron-Withdrawing Substituents.* In halogenations, electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type Z—CH_2—CH_3 are attacked predominantly or exclusively at the β position when Z is COOH, COCl, COOR, SO_2Cl, or CX_3. Such compounds as acetic acid and acetyl chloride are not attacked at all. This is in sharp contrast to electrophilic halogenations (**12-4–12-6**), where *only* the α position is substituted. This deactivation of a positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed on p. 939. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogens on carbon atoms next to electron-withdrawing groups have low electron densities (because of the field effect of Z) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the α and β carbons of propionic acid are:[90]

	CH_3—CH_2—COOH	
Me•	1	7.8
Cl•	1	0.02

It is possible to generate radicals adjacent to electron-withdrawing groups. Radical **14** can be generated and it undergoes coupling reactions with little selectivity. When **15** is generated, however, it rapidly disproportionates rather than couples, giving the corresponding alkene and alkane.[91] Such radicals have also been shown to have a conformational preference for orientation of the orbital containing the single electron. In such cases, hydrogen abstraction proceeds with good stereoselectivity.[92]



14



15

Some radicals, for example, *tert*-butyl,[93] benzyl,[94] and cyclopropyl,[95] are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms). The

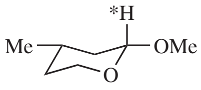
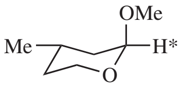
phenyl radical appears to have a very small degree of nucleophilic character.[96] For longer chains, the field effect continues, and the β position is also deactivated to attack by halogen, though much less so than the α position. We have already mentioned (p. 939) that abstraction of an α hydrogen atom from ring-substituted toluenes can be correlated by the Hammett equation.

5. *Stereoelectronic Effects*. On p. 1258, we will see an example of a stereoelectronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases, hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle (∼30°) with the unshared orbitals of the O or N much more easily than from those with a large angle (∼90°). For example, the starred hydrogen of **16** was abstracted ∼8 times faster than the starred hydrogen of **17**.[97]



16



17

The presence of an OR or SiR_3 substituent β- to the carbon bearing the radical accelerates the rate of halogen abstraction.[98]

Abstraction of a halogen has been studied much less,[99] but the order of reactivity is RI > RBr > RCl ≫ RF.

There are now many cases where free-radical reactions are promoted by transition metals.[100]

Reactivity at a Bridgehead[101]

Many free-radical reactions have been observed at bridgehead carbons, as in formation of bromide **18** (see **14-30**),[102] demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl

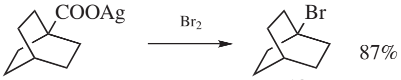
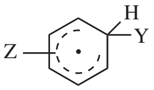
peroxide gave mostly 2-chloronorbornane, though the bridgehead position is tertiary.[103] So, while bridgehead free-radical substitution is possible, it is not preferred, presumably because of the strain involved.[104]



18

Reactivity in Aromatic Substrates

Free-radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; that is, we need to know which position on the ring will be attacked to give the intermediate, **19**.



19

The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent ortho, meta, and para isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free-radical substitutions because of the many side reactions. It may be, for example, that in a given case the ortho position is more reactive than the para, but the intermediate from the para attack may go on to product while that from ortho attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, though there has been much controversy over just how meaningful such conclusions are[105]

1. All substituents increase reactivity at ortho and para positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at meta positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and ortho–para directing; none are deactivating or (chiefly) meta directing.

TABLE 14.2. Partial Rate Factors for Attack of Substituted Benzenes by Phenyl Radicals Generated from Bz_2O_2[108]

	Partial Rate Factor		
Z	*o*	*m*	*p*
H	1	1	1
NO_2	5.50	0.86	4.90
CH_3	4.70	1.24	3.55
CMe_3	0.70	1.64	1.81
Cl	3.90	1.65	2.12
Br	3.05	1.70	1.92
MeO	5.6	1.23	2.31

3. Reactivity at ortho positions is usually somewhat greater than at para positions, except where a large group decreases ortho reactivity for steric reasons.

4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of para-disubstituted compounds XC_6H_4Y showed that substitution ortho to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).[106] The increase could be correlated with the Hammett σ_p values for X.

5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (see p. 677) are not great.[107] Partial rate factors for a few groups are given in Table 14.2.[108]

6. Although hydrogen is the leaving group in most free-radical aromatic substitutions, ipso attack (p. 671) and ipso substitution (e.g., with Br, NO_2, or CH_3CO as the leaving group) have been found in certain cases.[109]

Reactivity in the Attacking Radical[110]

We have already seen that some radicals are much more selective than others (p. 944). The bromine atom is so selective that when only primary hydrogens are available, as in neopentane or *tert*-butylbenzene, the reaction is slow or nonexistent; and isobutane can be selectively brominated to give *tert*-butyl bromide in high yields.

TABLE 14.3. Some Common Free Radicals in Decreasing Order of Activity[a]

	E			E	
Radical	kcal mol^{-1}e	kJ mol^{-1}e	Radical	kcal mol^{-1}	kJ mol^{-1}
F•	0.3	1.3	H•	9.0	38
Cl•	1.0	4.2	Me•	11.8	49.4
MeO•	7.1	30	Br•	13.2	55.2
CF_3•	7.5	31			

[a]The *E* values represent activation energies for the reaction

$$X\bullet + C_2H_6 \longrightarrow X\text{–}H + C_2H_5\bullet \qquad \text{(Ref. 112)}$$

i-Pr• is less active than Me• and *t*-Bu• still less so.[113]

However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes, for example, ethylbenzene and cumene, takes place exclusively at the a position,[111] emphasizing the selectivity of Br•. The dissociation energy *D* of the C—H bond is more important for radicals of low reactivity than for highly reactive radicals, since bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack α to an electron-withdrawing group because the energy of the C—H bond there is lower than in other places in the molecule.

Some radicals, for example, triphenylmethyl, are so unreactive that they abstract hydrogens very poorly if at all. Table 14.3 lists some common free radicals in approximate order of reactivity.[112]

It has been mentioned that some free radicals (e.g., chloro) are electrophilic and some (e.g., *tert*-butyl) are nucleophilic. It must be borne in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

The Effect of Solvent on Reactivity[114]

As noted earlier, the solvent usually has little effect on free-radical substitutions in contrast to ionic ones: indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference. Chlorination of 2,3-dimethylbutane in aliphatic solvents gave about 60% $(CH_3)_2CHCH(CH_3)CH_2Cl$

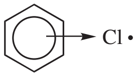
and 40% $(CH_3)_2CHCCl(CH_3)_2$, while in aromatic solvents the ratio became ~10:90.[115] This result is attributed to complex formation between the aromatic solvent and the



20

chlorine atom that makes the chlorine more selective.[116] This type of effect is not found in cases where the differences in ability to abstract the atom are caused by field effects of electron-withdrawing groups (p. 948). In such cases, aromatic solvents make little difference.[117] The complex **20** has been detected[118] as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in CCl_4.[119] Differences caused by solvents have also been reported in reactions of other radicals.[120] Some of the anomalous results obtained in the chlorination of aromatic side chains (p. 947) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.[121] Much smaller, though real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to CCl_4.[122] However, these differences are not caused by formation of a complex between Cl• and the solvent. There are cases,

however, where the rate of reaction for trapping a radical depends on the polarity of the solvent, particularly in water.[123]

REACTIONS

The reactions in this chapter are classified according to leaving group. The most common leaving groups are hydrogen and nitrogen (from the diazonium ion); these are considered first.

HYDROGEN AS LEAVING GROUP

A. Substitution by Halogen

14-1 Halogenation at an Alkyl Carbon[124]

Halogenation or **Halo-de-hydrogenation**

$$\text{R—H} \quad + \quad \text{Cl}_2 \xrightarrow{hv} \text{R—Cl}$$

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or UV light.[125] These reactions require a radical chain initiator, light, or higher temperatures.[126] The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: Not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariably occur even if there is a large molar ratio of substrate to halogen.

When functional groups are present, the principles are those outlined on p. 945; favored positions are those α to aromatic rings, while positions α to electron-withdrawing groups are least likely to be substituted. Tertiary carbons are most likely to be attacked and primary least. Positions α to an OR group are very readily attacked. Nevertheless, mixtures are nearly always obtained. This can be contrasted to the regioselectivity of electrophilic halogenation (**12-4–12-6**), which always takes place α to a carbonyl group (except when the reaction is catalyzed by $AgSbF_6$; see following). Of course, if a *mixture* of chlorides is wanted, the reaction is usually

[126]Hill, C.L. *Activation and Functionalization of Alkanes*, Wiley, NY, ***1989***.

quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen (e.g., ethane, cyclohexane, neopentane). The most common are methylbenzenes and other substrates with methyl groups on aromatic rings, since few cases are known where halogen atoms substitute at an aromatic position.[127] Of course, ring substitution *does* take place in the presence of a positive-ion-forming catalyst (**11-10**). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include H_2, alkenes, higher alkanes, lower alkanes, and halogen derivatives of these compounds. Solvent plays an important role in this process.[128]

The bromine atom is much more selective than the chlorine atom. As indicated on p. 952, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (p. 942) can operate.

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,[129] but seldom, because it is too reactive and hard to control.[130] It often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations too. Fluorination[131] has been achieved by the use of chlorine trifluoride ClF_3 at −75°C.[132] For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluoroxytrifluoromethane CF_3OF fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.[133] For example, adamantane gave 75% 1-fluoroadamantane. Fluorine at −70°C, diluted with N_2,[134] and bromine trifluoride at 25–35°C[135] are also highly regioselective for

tertiary positions. These reactions probably have electrophilic,[136] not free-radical mechanisms. In fact, the success of the F_2 reactions depends on the suppression of free radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers.

Iodine can be used if the activating light has a wavelength of 184.9 nm,[137] but iodinations using I_2 alone are seldom attempted, largely because the HI formed reduces the alkyl iodide. The direct free-radical halogenation of aliphatic hydrocarbons with iodine is significantly endothermic relative to the other halogens, and the requisite chain reaction does not occur.[138] On the other hand, when iodine, CCl_4•2 AlI_3 react with an alkane in dibromomethane at −20°C, good yields of the iodoalkane are obtained.[139] The reaction of an alkane with *tert*-butylhypoiodite (*t*-BuOI) at 40°C gave the iodoalkane in good yield.[140] The reaction of alkanes with iodine and $PhI(OAc)_2$ generates the iodoalkane.[141] A radical protocol was developed using CI_4 with base. Cyclohexane could be iodinated, for example, with CI_4 in the presence of powdered NaOH.[142] The reaction led to the use of iodoform on solid NaOH as the iodination reagent of choice. α-Iodo ethers and α-iodolactones have been prepared from the parent ether or lactone via treatment with Et_4N•4 HF under electrolytic conditions.[143]

Many other halogenation agents have been employed, the most common of which is sulfuryl chloride SO_2Cl_2.[144] A mixture of Br_2 and HgO is a more active brominating agent than bromine alone.[145] The actual brominating agent in this case is believed to be bromine monoxide Br_2O. Among other agents used have been *N*-bromosuccinimide (NBS, see **14-3**), CCl_4,[146] $BrCCl_3$,[147] PCl_5,[148] and *N*-haloamines and sulfuric acid.[149] In all these cases, a chain-initiating catalyst is required, usually peroxides or UV light.

A base-induced bromination has been reported. 2-Methyl butane reacts with 50% aq. NaOH and CBr_4, in a phase-transfer catalyst, to give a modest yields of 2-bromo-2-methylbutane.[150]

When chlorination is carried out with *N*-haloamines and sulfuric acid (catalyzed by either uv light or metal ions), selectivity is much greater than with other reagents.[149] In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the ω - 1 position).[151] Some typical selectivity values are[152]

$CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-CH_3$ Ref. 153
1 56 29 14

$CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-OH$ Ref. 154
1 92 3 1 1 2 0 0

$CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-COOMe$ Ref. 155
3 72 20 4 1 0

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,[156] and adamantane and bicyclo[2.2.2]octane at the bridgeheads[157] by this procedure. The reasons for the high ω - 1 specificity are not clearly understood.[158] Alkyl bromides can be regioselectively chlorinated one carbon away from the bromine (to give *vic*-bromochlorides) by treatment with PCl_5.[159] Alkyl chlorides can be converted to *vic*-dichlorides by treatment with $MoCl_5$.[160] Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil zeolite.[161] In another regioselective chlorination, alkanesulfonamides

[150]Schreiner, P.R.; Lauentstein, O.; Kolomitsyn, I.V.; Nadi, S.; Kokin, A.A. *Angew. Chem. Int. Ed.* ***1998***, *37*, 1895.

[151]The ω - 1 regioselectivity diminishes when the chains are >10 carbons; see Deno, N.C.; Jedziniak, E.J. *Tetrahedron Lett.* ***1976***, 1259; Konen, D.A.; Maxwell, R.J.; Silbert, L.S. *J. Org. Chem.* ***1979***, *44*, 3594.

[152]The ω − 1 selectivity values shown here may actually be lower than the true values because of selective solvolysis of the ω − 1 chlorides in concentrated H_2SO_4: see Deno, N.C.; Pohl, D.G. *J. Org. Chem.* ***1975***, *40*, 380.

[161]Turro, N.J.; Fehlner, J.R.; Hessler, D.P.; Welsh, K.M.; Ruderman, W.; Firnberg, D.; Braun, A.M. *J. Org. Chem.* ***1988***, *53*, 3731.

RCH_2-$CH_2CH_2SO_2NHR'$ are converted primarily to $RCHClCH_2CH_2SO_2NHR'$ by sodium peroxydisulfate $Na_2S_2O_8$ and $CuCl_2$.[162] For regioselective chlorination at certain positions of the steroid nucleus, see **19-2**.

In almost all cases, the mechanism involves a free-radical chain:

$$\text{Initiation} \quad X_2 \xrightarrow{h\nu} 2\,X\bullet$$

$$RH + X\bullet \longrightarrow R\bullet + XH$$

$$\text{Propagation} \quad R\bullet + X_2 \longrightarrow RX + X\bullet$$

$$\text{Termination} \quad R\bullet + X\bullet \longrightarrow RX$$

When the reagent is halogen, initiation occurs as shown above.[163] When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *tert*-butyl hypochlorite (*t*-BuOCl) have been formulated as[164]

$$RH + t\text{-}BuO\bullet \longrightarrow R\bullet + t\text{-}BuOH$$

$$R\bullet + t\text{-}BuOCl \longrightarrow RCl + t\text{-}BuO\bullet$$

and the abstracting radicals in the case of *N*-haloamines are the aminium radical cations $R_2NH\bullet^+$ (p. 693), with the following mechanism (in the case of initiation by Fe^{2+}):[149]

$$\text{Initiation} \quad R_2NCl \xrightarrow{H^+} R_2\overset{\oplus}{N}HCl \xrightarrow{Fe^{2+}} R_2NH\bullet^+ + \overset{\oplus}{Fe}Cl$$

$$R_2NH\bullet^+ + RH \longrightarrow R_2NH_2 + R\bullet$$

$$\text{Propagation} \quad R\bullet + R_2NHCl \longrightarrow RCl + R_2NH\bullet^+$$

This mechanism is similar to that of the Hofmann–Löffler reaction (**18-40**).

The two propagation steps shown above for X_2 are those that lead directly to the principal products (RX and HX), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to RX, but any two radicals may combine (•H, •CH_3, •Cl, •CH_2CH_3 in all combinations).

[162]Nikishin, G.I.; Troyansky, E.I.; Lazareva, M.I. *Tetrahedron Lett.* ***1985***, *26*, 3743.

[163]There is evidence (unusually high amounts of multiply chlorinated products) that under certain conditions in the reaction of RH with Cl_2, the products of the second propagation step (RX + X•) are enclosed within a solvent cage. See Skell, P.S.; Baxter III, H.N. *J. Am. Chem. Soc.* ***1985***, *107*, 2823; Raner, K.D.; Lusztyk, J.; Ingold, K.U. *J. Am. Chem. Soc.* ***1988***, *110*, 3519; Tanko, J.M.; Anderson III, F.E. *J. Am. Chem. Soc.* ***1988***, *110*, 3525.

[164]Carlsson, D.J.; Ingold, K.U. *J. Am. Chem. Soc.* ***1967***, *89*, 4885, 4891; Walling, C.; McGuiness, J.A. *J. Am. Chem. Soc.* ***1969***, *91*, 2053. See also, Zhulin, V.M.; Rubinshtein, B.I. *Bull. Acad. Sci. USSR Div. Chem. Sci*, ***1977***, *26*, 2082.

Thus, products like H_2, higher alkanes, and higher alkyl halides can be accounted for. When methane is the substrate, the rate-determining step is

$$CH_4 + Cl\cdot \longrightarrow \cdot CH_3 + HCl$$

since an isotope effect of 12.1 was observed at 0°C.[165] For chlorinations, chains are very long, typically 10^4–10^6 propagations before a termination step takes place.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane, ΔH values for the two principal propagation steps are

	kcal mol^{-1}				kJ mol^{-1}			
Reaction	F_2	Cl_2	Br_2	I_2	F_2	Cl_2	Br_2	I_2
$CH_4 + X\bullet \rightarrow CH_3\bullet + HX$	−31	+2	+17	+34	−132	+6	+72	+140
$CH_4 + X_2 \rightarrow CH_3X + X\bullet$	−70	−26	−24	−21	−293	−113	−100	−87

In each case, D for CH_3—H is 105 kcal mol^{-1} (438 kJ mol^{-1}), while D values for the other bonds involved are given in Table 14.4.[166] Fluorine is so reactive[167] that neither uv light nor any other initiation is needed (total $\Delta H = -101$ kcal mol^{-1}; −425 kJ mol^{-1});[168] while Br_2 and I_2 essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for Br_2 and I_2. It is apparent that the most important single factor causing the order of halogen reactivity to be $F_2 > Cl_2 > Br_2 > I_2$ is the decreasing strength of the HX bond in the order HF > HCl > HBr > HI. The increased reactivity of secondary and tertiary positions is in accord with the decrease in D values for R—H in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination step 1 is exothermic for practically all substrates other than CH_4, since most other aliphatic C—H bonds are weaker than those in CH_4.)

Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by $AgSbF_6$.[169] Direct

[165]Wiberg, K.B.; Motell, E.L. *Tetrahedron* ***1963***, *19*, 2009.

[166]Kerr, J.A., in Weast, R.C. *Handbook of Chemistry and Physics*, 69th ed., CRC Press, Boca Raton, FL, ***1988***, pp. F174–F189.

[167]It has been reported that the reaction of F atoms with CH_4 at 25 K takes place with practically zero activation energy: Johnson, G.L.; Andrews, L. *J. Am. Chem. Soc.* ***1980***, *102*, 5736.

[168]For F_2, the following initiation step is possible: $F_2 + RH \rightarrow R\bullet + F\bullet$ + HF [first demonstrated by Miller, Jr, W.T.; Koch, Jr, S.D.; McLafferty, F.W. *J. Am. Chem. Soc.* ***1956***, *78*, 4992]. ΔH for this reaction is equal to the small positive value of 5 kcal mol^{-1} (21 kJ mol^{-1}). The possibility of this reaction (which does not require an initiator) explains why fluorination can take place without UV light [which would otherwise be needed to furnish the 38 kcal mol^{-1} (159 kJ mol^{-1}) necessary to break the F—F bond]. Once the reaction has been initiated, the large amount of energy given off by the propagation steps is ample to cleave additional F_2 molecules. Indeed, it is the magnitude of this energy that is responsible for the cleavage of carbon chains by F_2.

chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneseleninyl chloride PhSe(O)Cl and $AlCl_3$ or $AlBr_3$.[170] However, while some substituted alkenes give high yields of chloro substitution products, others (e.g., styrene) undergo addition of Cl_2 to the double bond (**15-39**).[131] Electrophilic fluorination has already been mentioned (p. 956).

14-2 Halogenation at Silicon

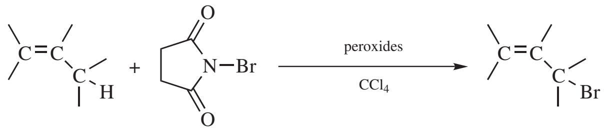
Halogenation or **Halo-de-hydrogenation**

$$R_3Si\text{–}H \longrightarrow R_3Si\text{–}X$$

Just as free-radical halogenation occurs at the carbon of an alkane, via hydrogen abstraction to form the radical, a similar reaction occurs at silicon. When triisopropylsilane (*i*Pr_3Si—H) reacts with *tert*-butyl hypochlorite at −10°C, the product is triisopropylchlorosilane (*i*Pr_3Si—Cl).[171]

14-3 Allylic and Benzylic Halogenation

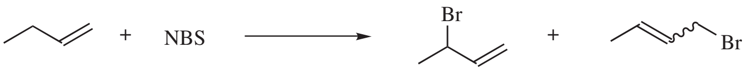
Halogenation or **Halo-de-hydrogenation**



[170]Kamigata, N.; Satoh, T.; Yoshida, M. *Bull. Chem. Soc. Jpn.* ***1988***, *44*, 449.
[171]Chawla, R.; Larson, G.L. *Synth. Commun.* ***1999***, *29*, 3499.

This reaction is a special case of **14-1**, but is important enough to be treated separately.[172] Alkenes can be halogenated in the allylic position and also a benzylic position by a number of reagents, of which NBS[173] is by far the most common. When this reagent is used, the reaction is known as *Wohl–Ziegler bromination*. A nonpolar solvent is used, most often CCl_4, but the reaction has been done in an ionic liquid.[174] A variation in the reaction used NBS with 5% $Yb(OTf)_3$ and 5% $ClSiMe_3$.[175] Other *N*-bromo amides have also been used. Allylic chlorination has been carried out, with *N*-chlorosuccinimide, *tert*-butyl hypochlorite,[176] or with $NaClO/CeCl_3{\bullet}7\ H_2O$.[177] With any reagent an initiator is needed; this is usually AIBN (**1**), a peroxide, such as di-*tert*-butyl peroxide or benzoyl peroxide or, less often, UV light.

The reaction is usually quite specific at an allylic or benzylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained, **21** and **22**.



21 **22**

When a double bond has two different allylic positions (e.g., $CH_3CH{=}CHCH_2CH_3$), a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.[178] It is possible to brominate both sides of the double bond.[179] Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than α to the first bromine. Molecules with a benzylic hydrogen, such as toluene, react rapidly to give α-bromomethyl benzene (e.g., $PhCH_3 \rightarrow PhCH_2Br$).

N-Bromosuccinimide is also a highly regioselective brominating agent at other positions, including positions α to a carbonyl group, to a $C{\equiv}C$ triple bond, and to an aromatic ring (benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is α to the triple bond.[180]

Dauben and McCoy demonstrated that the mechanism of allylic bromination is of the free-radical type,[181] showing that the reaction is very sensitive to free-radical

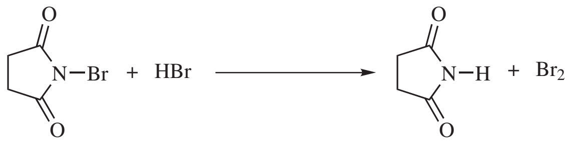
initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the substrate is the bromine atom. The reaction is initiated by small amounts of Br•. Once it is formed, the main propagation steps are

Step 1 $$Br\bullet + RH \longrightarrow R\bullet + HBr$$

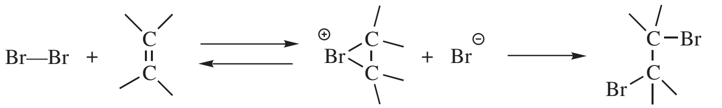
Step 2 $$R\bullet + Br_2 \longrightarrow RBr + Br\bullet$$

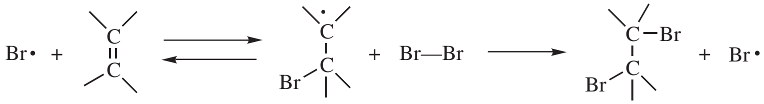
The source of the Br_2 is a fast ionic reaction between NBS and the HBr liberated in step 1:



The function of the NBS is therefore to provide a source of Br_2 in a low, steady-state concentration and to use up the HBr liberated in step 1.[182] The main evidence for this mechanism is that NBS and Br_2 show similar selectivity[183] and that the various *N*-bromo amides also show similar selectivity,[184] which is consistent with the hypothesis that the same species is abstracting in each case.[185]

It may be asked why, if Br_2 is the reacting species, it does not add to the double bond, either by an ionic or by a free-radical mechanism (see **15-39**). Apparently the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free radical:





[182]This mechanism was originally suggested by Adam, J.; Gosselain, P.A.; Goldfinger, P. *Nature (London)*, ***1953***, *171*, 704; *Bull. Soc. Chim. Belg.* ***1956***, *65*, 533.

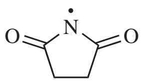
[184]Walling, C.; Rieger, A.L. *J. Am. Chem. Soc.* ***1963***, *85*, 3134; Pearson, R.; Martin, J.C. *J. Am. Chem. Soc.* ***1963***, *85*, 3142; Incremona, J.H.; Martin, J.C. *J. Am. Chem. Soc.* ***1970***, *92*, 627.

[185]For other evidence, see Day, J.C.; Lindstrom, M.J.; Skell, P.S. *J. Am. Chem. Soc.* ***1974***, *96*, 5616.

The other bromine atom comes from another bromine-containing molecule or ion. This is clearly not a problem in reactions with benzylic species since the benzene ring is not prone to such addition reactions. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an alkene in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is removed as it is formed so that it is not available to complete the addition step. This has indeed been demonstrated.[186]



23

When NBS is used to brominate non-alkenyl substrates, such as alkanes, another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical[187] **23** can operate.[188] This mechanism is facilitated by solvents (e.g., CH_2Cl_2, $CHCl_3$, or MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene). The alkene serves to scavenge any Br• that forms from the reagent. Among the evidence for the mechanism involving **23** are abstraction selectivities similar to those of Cl• atoms and the isolation of β-bromopropionyl isocyanate ($BrCH_2CH_2CONCO$) which is formed by ring opening of **23**.

Allylic chlorination has also been carried out[189] with *N*-chlorosuccinimide (NCS) and either arylselenyl chlorides (ArSeCl), aryl diselenides (ArSeSeAr), or TsNSO as catalysts. Use of the selenium catalysts produces almost entirely the allylically rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide Cl_2O, with no catalyst, also gives allylically rearranged chlorides in high yields.[190] A free-radical mechanism is unlikely in these reactions.

Allyl silanes react with transition metals bearing chlorine ligands to give allyl chlorides, where a chlorine replaces a Me_3Si unit.[191]

14-4 Halogenation of Aldehydes

Halogenation or **Halo-de-hydrogenation**

$$RCHO + Cl_2 \longrightarrow RCOCl$$

The α-halogenation reaction of carbonyl compounds was mentioned in Section **14-2**. A different halogenation reaction is possible in which aldehydes can be directly converted to acyl chlorides by treatment with chlorine, but the reaction operates only when the aldehyde does not contain an α hydrogen and even then it is not very useful. When there is an α hydrogen, α halogenation (**14-2, 12-4**) occurs instead. Other sources of chlorine have also been used, among them SO_2Cl_2[192] and *t*-BOCl.[193] The mechanisms are probably of the free-radical type. *N*-Bromosuccinimide, with AIBN (p. 935) as a catalyst, has been used to convert aldehydes to acyl bromides.[194]

OS **I**, 155.

B. Substitution by Oxygen

14-5 Hydroxylation at an Aromatic Carbon[195]

Hydroxylation or **Hydroxy-de-hydrogenation**

$$ArH + H_2O_2 + FeSO_4 \longrightarrow ArOH$$

A mixture of hydrogen peroxide and ferrous sulfate,[196] called *Fenton's reagent*,[197] can be used to hydroxylate aromatic rings, though yields are usually not high.[198] Biaryls are usually side products.[199] Among other reagents used have been H_2O_2 and titanous ion; O_2 and Cu(I)[200] or Fe(III),[201] a mixture of ferrous

ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*);[202] O_2 and KOH in liquid NH_3;[203] and peroxyacids such as peroxynitrous and trifluoroperoxyacetic acids.

Much work has been done on the mechanism of the reaction with Fenton's reagent, and it is known that free aryl radicals (formed by a process, e.g., HO• + ArH → AR• + H_2O) are not intermediates. The mechanism is essentially that outlined on p. $$$, with HO• as the attacking species,[204] formed by

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^- + HO\bullet$$

The rate-determining step is formation of HO• and not its reaction with the aromatic substrate.

An alternative oxidation of arene to phenol was reported using $Cu(NO_3)\bullet 3\ H_2O$, 30% hydrogen peroxide and a phosphate buffer.[205]

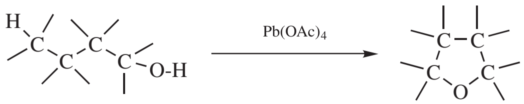
14-6 Formation of Cyclic Ethers

(5)*OC-cyclo*-Alkoxy-de-hydro-substitution



Alcohols with a hydrogen in the δ position can be cyclized with lead tetraacetate.[206] The reaction is usually carried out at ~80°C (most often in refluxing benzene), but can also be done at room temperature if the reaction mixture is irradiated with uv light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when γ and ε hydrogens are present. The reaction has also been carried out with a mixture of halogen (Br_2 or I_2) and a salt or oxide of silver or mercury (especially HgO or AgOAc),[207] with iodosobenzene diacetate and I_2,[208] and with ceric

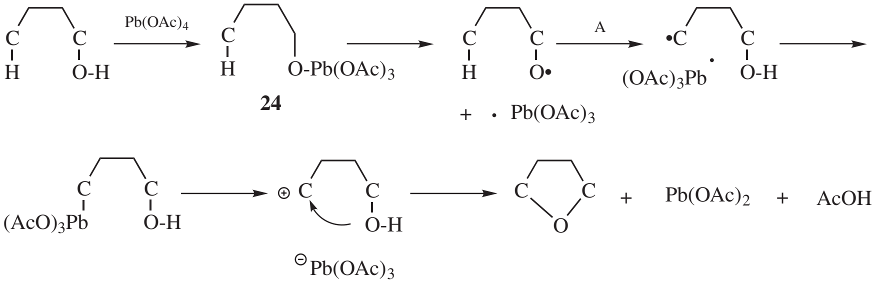
ammonium nitrate (CAN).[209] The following mechanism is likely for the lead tetraacetate reaction:[210]



though **24** has never been isolated. The step marked **A** is a 1,5 internal hydrogen abstraction. Such abstractions are well known (see **18-40**) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6 abstractions).[211]

Reactions that sometimes compete are oxidation to the aldehyde or acid (**19-3** and **19-22**) and fragmentation of the substrate. When the OH group is on a ring of at least seven members, a transannular product can be formed, as in the cyclization reaction of 1-octanol to **25**.[212]

25

β-Hydroxy ethers can give cyclic acetals, such as **26**.[213]

14-7 Formation of Hydroperoxides

Hydroperoxy-de-hydrogenation

$$RH + O_2 \longrightarrow R{-}O{-}O{-}H$$

The slow atmospheric oxidation (*slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.[214] The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. Most autoxidations proceed by free-radical chain processes that involve peroxyl radicals.[215] To suppress autoxidation, an antioxidant can be added that will prevent or retard the reaction with atmospheric oxygen.[216] Although some lactone compounds are sold as antioxidants, many radicals derived from lactones show poor or no reactivity toward oxygen.[216] The hydroperoxides produced often react further to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.[217] It is because of autoxidation that foods, rubber, paint, lubricating oils, and so on deteriorate on exposure to the atmosphere over periods of time. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes. As with other free-radical reactions of C—H bonds, some bonds are attacked more readily than others,[218] and these are the ones we have seen before (pp. 943–949), though the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,[219] and allylic (though allylic rearrangements are common) R.[220] 2-Phenylpropane reacted with oxygen to give $PhMe_2C$—OOH, for example. Another susceptible position is aldehydic C—H,

[214]The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. See Goosen, A.; Morgan, D.H. *J. Chem. Soc. Perkin Trans. 2* ***1994***, 557. [219]For a method that gives good yields at benzylic positions, see Santamaria, J.; Jroundi, R.; Rigaudy, J. *Tetrahedron Lett.* ***1989***, *30*, 4677.

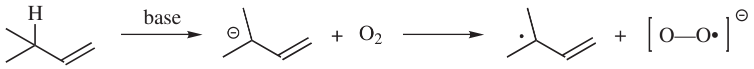
[220]For a review of autoxidation at allylic and benzylic positions, see Voronenkov, V.V.; Vinogradov, A.N.; Belyaev, V.A. *Russ. Chem. Rev.* ***1970***, *39*, 944.

but the peroxyacids so produced are not easily isolated[221] since they are converted to the corresponding carboxylic acids (**19-23**). The α positions of ethers are also easily attacked by oxygen [RO—C—H → RO—C—OOH], but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.[222]

Oxygen itself (a diradical) is not reactive enough to be the species that actually abstracts the hydrogen. But if a trace of free radical (say R′•) is produced by some initiating process, *it* reacts with oxygen[223] to give R′—O—O•; since this type of radical *does* abstract hydrogen, the chain is

$$R'OO\bullet + RH \longrightarrow R\bullet + R'OOH$$
$$R\bullet + O_2 \longrightarrow R{-}O{-}O\bullet$$
$$\text{etc.}$$

In at least some cases (in alkaline media)[224] the radical R• can be produced by formation of a carbanion and its oxidation (by O_2) to a radical, such as allylic radical **27**.[225]



27

Autoxidations in alkaline media can also proceed by a different mechanism: $R{-}H + \text{base} \rightarrow R^- + O_2 \rightarrow ROO^-$.[226]

When alkenes are treated with oxygen that has been photosensitized (p. 341), they are substituted by OOH in the allylic position in a synthetically useful reaction.[227] Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not

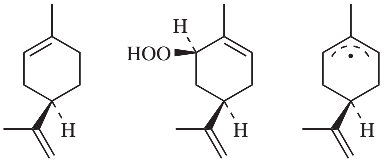
the ground-state oxygen (a triplet), but an excited singlet state[228] (in which all electrons are paired), and the function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,[229] for example, by the reaction between H_2O_2 and NaOCl[230] or sodium molybdate,[231] or between ozone and triphenyl phosphite.[232] Calcium peroxide diperoxohydrate (CaO_2,2 H_2O_2) has been reported as a storable compound used for the chemical generation of singlet oxygen.[233] The oxygen generated by either photochemical or nonphotochemical methods reacts with alkenes in the same way;[234] this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free-radical mechanism, and



28 **29** **30**

further evidence that free radicals are not involved comes from the treatment of optically active limonene (**28**) with singlet oxygen. Among other products is the optically active hydroperoxide **29**, though if **30** were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.[235] In contrast, autoxidation of **28** gave optically inactive **29** (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures). As this example shows, singlet oxygen reacts faster with more-highly substituted than with less-highly substituted alkenes. The order of alkene reactivity is

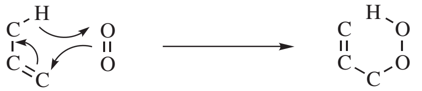
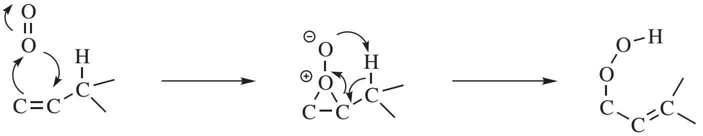
tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the alkene.[236] In simple trisubstituted alkenes, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.[237] With *cis*-alkenes of the form RCH=CHR′, the hydrogen is removed from the larger R group.[238] Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).[239] Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.[240]



Several mechanisms have been proposed for the reaction with singlet oxygen.[241] One of these is a pericyclic mechanism, similar to that of the ene synthesis (**15-23**) and to the first step of the reaction between alkenes and SeO_2 (**19-14**). However, there is strong evidence against this mechanism,[242] and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (**31**),[243] followed by internal proton transfer.[244]



31

Still other proposed mechanisms involve diradicals or dipolar intermediates.[245]

14-8 Formation of Peroxides

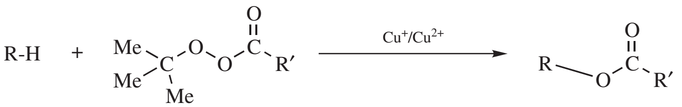
Alkyldioxy-de-hydrogenation

$$RH + R'OOH \xrightarrow{CuCl} ROOR'$$

Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts, for example, cobalt and manganese salts.[246] Very high yields can be obtained. The type of hydrogen replaced is similar to that with NBS (**14-3**), that is, mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free-radical type, involving ROO• formed from ROOH and the metal ion. The reaction can be used to demethylate tertiary amines of the form R_2NCH_3, since the product R_2NHCH_2OOR' can easily be hydrolyzed by acid (**10-6**) to give R_2NH.[247]

14-9 Acyloxylation

Acyloxylation or Acyloxy-de-hydrogenation



Susceptible positions of organic compounds can be directly acyloxylated[248] by *tert*-butyl peroxyesters, the most frequently used being acetic and benzoic (R′ = Me or Ph).[249] The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without it is not selective. Susceptible positions are similar to those in **14-6**: benzylic, allylic, and the a position of ethers and sulfides. Terminal alkenes are substituted almost entirely in the 3 position, that is, with only a small amount of allylic rearrangement, but internal alkenes generally give mixtures containing a large amount of allylic-shift product. If the reaction with alkenes is carried out in an excess of

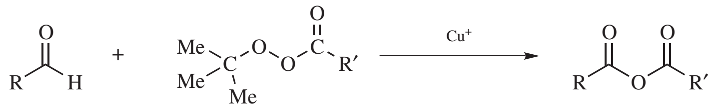
another acid R″COOH, the ester produced is of *that* acid ROCOR″. Aldehydes give anhydrides:



Acyloxylation has also been achieved with metallic acetates, such as lead tetraacetate,[250] mercuric acetate,[251] and palladium(II) acetate.[252] In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those α to an OR or SR group, but also at positions α to the carbonyl groups of aldehydes, ketones, or esters and at those a to two carbonyl groups (ZCH_2Z'). It is likely that in the latter cases it is the enol forms that react. Ketones can be α-acyloxylated indirectly by treatment of various enol derivatives with metallic acetates, for example, silyl enol ethers with silver carboxylates-iodine,[253] enol thioethers with lead tetraacetate,[254] and enamines[255] with lead tetraacetate[256] or thallium triacetate.[257] α,β-Unsaturated ketones can be acyloxylated in good yields in the α′ position with manganese triacetate.[258] Palladium acetate converts alkenes to vinylic and/or allylic acetates.[259] Lead tetraacetate even acyloxylates alkanes, in a slow reaction (10 days to 2 weeks), with tertiary and secondary positions greatly favored over primary ones.[260] Yields are as high as 50%. Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.[261]

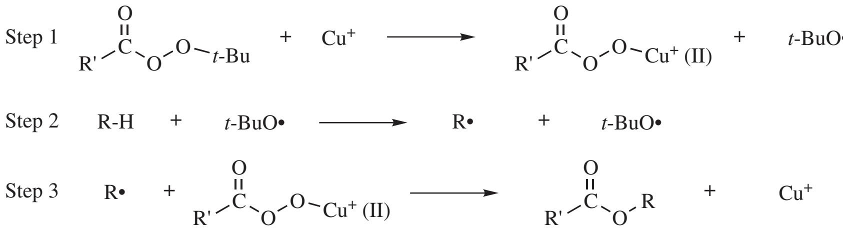
Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the following:[262]



32

This mechanism, involving a free radical R•, is compatible with the allylic rearrangements found.[263] The finding that *tert*-butyl peroxyesters labeled with ^{18}O in the carbonyl oxygen gave ester with 50% of the label in each oxygen[264] is in accord with a combination of R• with the intermediate **32**, in which the copper is ionically bound, so that the oxygens are essentially equivalent. Other evidence is that *tert*-butoxy radicals have been trapped with dienes.[265] Much less is known about the mechanisms of the reactions with metal acetates.[266]

Free-radical acyloxylation of aromatic substrates[267] has been accomplished with a number of reagents including copper(II) acetate,[268] benzoyl peroxide-iodine,[269] silver(II) complexes,[270] and cobalt(III) trifluoroacetate.[271]

The chlorosulfonation of organic molecules with chlorine and sulfur dioxide is called the *Reed reaction*.[272] In scope and range of products obtained, the reaction is similar to **14-1**. The mechanism is also similar, except that there are two additional main propagation steps:

$$\mathrm{R}\bullet + \mathrm{SO_2} \longrightarrow \mathrm{R{-}SO_2}\bullet$$
$$\mathrm{R{-}SO_2}\bullet + \mathrm{Cl_2} \longrightarrow \mathrm{R{-}SO_2Cl} + \mathrm{Cl}\bullet$$

Chlorosulfenation[273] can be accomplished by treatment with SCl_2 and UV light: $\mathrm{RH} + \mathrm{SCl_2} \xrightarrow{h\nu} \mathrm{RSCl}$.

D. Substitution by Nitrogen

14-11 The Direct Conversion of Aldehydes to Amides

Amination or **Amino-de-hydrogenation**

$$\mathrm{ArCHO} \xrightarrow[\text{NBS−AIBN}]{\mathrm{NH_3}} \mathrm{ArCONH_2}$$

Aliphatic and aromatic aldehydes have been converted to the corresponding amides with ammonia or a primary or secondary amine, NBS, and a catalytic amount of AIBN (p. 935).[274] In a reaction of more limited scope, amides are obtained from aromatic and α,β-unsaturated aldehydes by treatment with dry ammonia gas and nickel peroxide.[275] Best yields (80–90%) are obtained at −25 to −20°C. In the nickel peroxide reaction the corresponding alcohols ($ArCH_2OH$) have also been used as substrates.

The reaction has also been performed with MnO_2 and NaCN along with ammonia or an amine at 0°C in isopropyl alcohol.[276] Aldehydes were also shown to react with hydroxylamine hydrochloride at 140°C in the presence of aluminum oxide and methanesulfonic acid.[277] Treatment of a aldehyde with iodine in aqueous ammonia, followed by oxidation with aqueous hydrogen peroxide generates a primary amide.[278] Secondary amines react with aldehydes to the an amide in using a palladium catalyst[279] or a rhodium catalyst.[280] For an indirect way of converting aldehydes to amides, see **12-32**. Thioamides $RCSNR'_2$ have been prepared in good yield

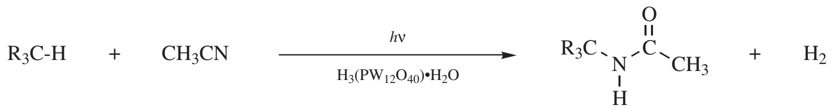
from thioaldehydes (produced *in situ* from phosphoranes and sulfur) and secondary amines.[281]

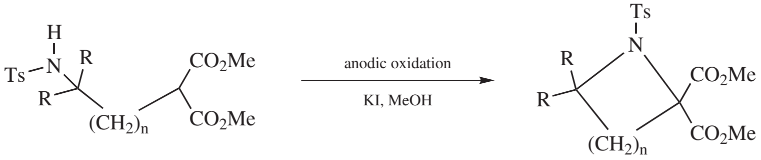
14-12 Amidation and Amination at an Alkyl Carbon

Acylamino-de-hydrogenation



When alkanes bearing a tertiary hydrogen are exposed to UV light in acetonitrile containing a heteropolytungstic acid, they are amidated.[282] The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogens, alkenes are formed (by loss of two hydrogens), rather than amides (**19-2**). Amidyl radicals can be generated by other means.[283]

An electrochemical method for amination has been reported by Shono and coworkers.[284] Derivatives of malonic esters containing an *N*-tosyl group were cyclized in high yields by anodic oxidation:



Three-, four-, and five-membered rings were synthesized by this procedure.

14-13 Substitution by Nitro

Nitro-de-carboxylation

In a reaction termed a "nitro-Hunsdiecker" (see **14-30**), vinyl carboxylic acids (conjugated acids) are treated with nitric acid and a catalytic amount of AIBN (p. 935). The product is the vinyl nitro compound, generated via decarboxylation of a radical intermediate.[285]

E. Substitution by Carbon

In these reactions, a new carbon–carbon bond is formed and they may be given the collective title *coupling reactions*. In each case, an alkyl or aryl radical is generated and then combines with another radical (a termination process) or attacks an aromatic ring or alkene to give the coupling product.[286]

14-14 Simple Coupling at a Susceptible Position

De-hydrogen-coupling

$$2\ \text{RH} \longrightarrow \text{R—R}$$

Alkane and alkyl substrates RH are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from RH to give R•, which dimerizes. Dialkyl and diacyl peroxides have been used, as well as Fenton's reagent (p. 964). This reaction is far from general, though in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,[287] as well as those α to a phenyl group (especially if there is also an α-alkyl or α-chloro group),[288] an ether group,[289] a carbonyl group,[290] a cyano group,[291] a dialkylamino group,[292] or a carboxylic ester group, either the acid or alcohol side.[293] Cross-coupling is possible in some cases. When toluene was heated with allyl bromide, in the presence of di-*tert*-butyl peroxide, 4-phenyl-1-butene was formed quantitatively.[294]

Conjugated amide were coupled via the γ-carbon to give good yields of the dimeric diamide, with an excess of samarium (II) iodide, and with modest enantioselectivity using a chiral additive.[295]

$$2\ \text{RH} \xrightarrow[\text{Hg}]{h\nu} \text{R—R} + H_2$$

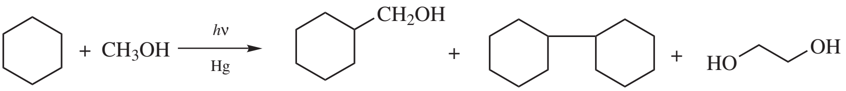
Alkanes can be dimerized by vapor-phase mercury photosensitization[296] in a synthetically useful process. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogens (e.g., cyclohexane) also give good yields. Dimerization of *n*-alkanes gives secondary-secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. Alcohols and ethers dimerize at the position α to the oxygen [e.g., 2 EtOH → MeCH(OH)CH(OH)Me].

When a mixture of compounds is treated, cross-dimerization (to give **33**) and homodimerization take place statistically.



33

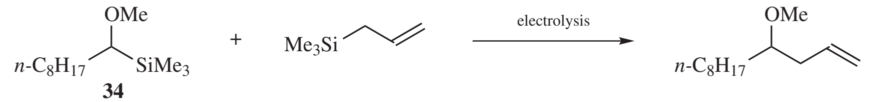
Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross-coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product (**10-6**) gives an aldehyde, thus achieving the conversion RH → RCHO. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals.

The reaction has been extended to ketones, carboxylic acids and esters (all of which couple a to the C=O group), and amides (which couple α to the nitrogen) by running it in the presence of H_2.[297] Under these conditions it is likely that the excited Hg abstracts H• from H_2, and that the remaining H• abstracts H from the substrate. Radicals have also been generated at benzylic positions and shown to couple with epoxides, forming an alcohol.[298]

OS **IV**, 367; **V**, 1026; **VII**, 482.

14-15 Coupling at a Susceptible Position Via Silanes

De-silyl-coupling



34

Under electrochemical conditions it is possible to couple two silanes. The reaction of **34** and allyltrimethylsilane, for example, gave the corresponding homoallylic ether.[299]

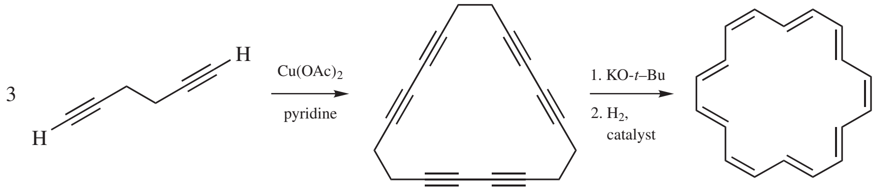
14-16 Coupling of Alkynes[300]

De-hydrogen-coupling

$$2\ R{-}C{\equiv}C{-}H \xrightarrow[\text{pyridine}]{CuX_2} R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes in high yields, is called the *Eglinton reaction*.[301] The large-ring annulenes of Sondheimer et al. (see p. 71) were prepared by rearrangement and hydrogenation of cyclic polyynes,[302] prepared by the Eglinton reaction with terminal diynes to give **35**, a cyclic trimer of 1,5-hexadiyne.[303] The corresponding tetramers (C_{24}), pentamers (C_{30}), and hexamers (C_{36}) were also formed. The Eglinton reaction is of wide scope. Many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen.



35

Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent, such as permanganate or hydrogen peroxide is required in the latter procedure. This method is not satisfactory for cyclic coupling. Hydrogen peroxide, potassium permanganate, potassium ferricyanide, iodine or Cu(II) can be used instead of oxygen as oxidants.[304] Isolation of copper acetylide during the reaction can be avoided by doing the reaction in pyridine or cyclohexylamine, in the presence of catalytic amount of

$CuCl_3$.[305] If the Glaser reaction is done with a *N*,*N*,*N'*,*N'*-tetramethylethylenediamine–CuCl complex, the reaction proceeds in good yield in virtually any organic solvent.[306] When molecular oxygen is the oxidant, this modification of Glaser condensation is known as the *Hay reaction*. A variation couples terminal alkynes using $CuCl_2$ in supercritical CO_2 (see p. 414),[307] and in ionic liquids.[308] Coupling was also achieved using $CuCl_2$ on KF—Al_2O_3 with microwave irradiation.[309] Homocoupling of alkynyl amines $R_2N—C{\equiv}CH$ to give the diyne $R_2N—C{\equiv}C—C{\equiv}C\text{-}NR_2$ was reported in aerated acetone with 10% CuI and 20% TMEDA.[310]

Unsymmetrical diynes can be prepared by *Cadiot–Chodkiewicz* coupling:[311]

$$R{-}C{\equiv}C{-}H \quad + \quad R'{-}C{\equiv}C{-}Br \xrightarrow{Cu^+} R{-}C{\equiv}C{-}C{\equiv}C{-}R' \quad + \quad HBr$$

This may be regarded as a variation of **10-74**, but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not, which is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. One version of this reaction binds the alkynyl bromide unit to a polymer, and the di-yne is released from the polymer after the solid state transformation.[312] Alkynes have also been coupled using CuI and a palladium catalyst.[313] Propargyl halides also give the reaction,[314] as do 1-bromo propargylic alcohols ($Br—C{\equiv}C—CH_2OH$).[315] A variation of the Cadiot–Chodkiewicz method consists of treating a haloalkyne ($R'C{\equiv}CX$) with a copper acetylide ($RC{\equiv}CCu$).[316] The Cadiot–Chodkiewicz procedure can be adapted to the preparation of diynes in which $R' = H$ by the use of $BrC{\equiv}CSiEt_3$ and subsequent cleavage of the $SiEt_3$ group.[317] This protecting group can also be used in the Eglinton or Glaser methods.[318]

The mechanism of the Eglinton and Glaser reactions probably begins with loss of a proton

$$R{-}C{\equiv}C{-}H \xrightarrow{\text{base}} R{-}C{\equiv}C^-$$

since there is a base present and acetylenic protons are acidic. It is known, of course, that cuprous ion can form complexes with triple bonds. The last step is probably the coupling of two radicals:

$$R{-}C{\equiv}C\bullet \longrightarrow R{-}C{\equiv}C{-}C{\equiv}C{-}R$$

but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,[319] and depend on the oxidizing agent. One proposed mechanism postulated Cu(II) as the oxidant.[320] It has been shown that molecular oxygen forms adducts with Cu(I) supported by tertiary amines, which might be the intermediates in the Glaser reaction where molecular oxygen is the oxidant.[321] For the Hay reaction, the mechanism involves a $Cu^{I}/Cu^{III}/Cu^{II}/Cu^{I}$ catalytic cycle, and the key step for this reaction is the dioxygen activation during complexation of two molecules of acetylide with molecular oxygen, giving a Cu(III) complex.[322] This mechanism is supported by isolation and characterization of Cu(III) complexes formed under the conditions of the Glaser coupling.

Terminal alkynes are not the only reaction partners. 1-Trimethylsilyl alkynes (R—C≡C—$SiMe_3$) give the diyne R—C≡C—C≡C—R) upon reaction with CuCl[323] or $Cu(OAc)_2/Bu_4NF$.[324]

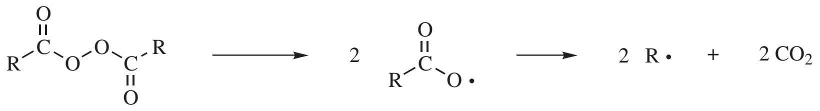
the scope is similar. When R = alkyl, the scope is more limited.[326] Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown on p. 940 (CIDNP has been observed[327]); the radicals are produced by



Since no relatively stable free radical is present (such as •O—N=N—Ar in **13-27**), most of the product arises from dimerization and disproportionation.[328] The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts the hydrogen from **5** and reduces the extent of side reactions.[329]

$$\text{ArH} + \text{Ar}'\text{Pb(OAc)}_3 \longrightarrow \text{ArAr}'$$

Aromatic compounds can also be arylated by aryllead tricarboxylates.[330] Best yields (~70–85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely. Phenols are phenylated ortho to the OH group (and enols are a phenylated) by triphenylbismuth dichloride or by certain other Bi(V) reagents.[331] *O*-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free-radical mechanism is unlikely.[332]

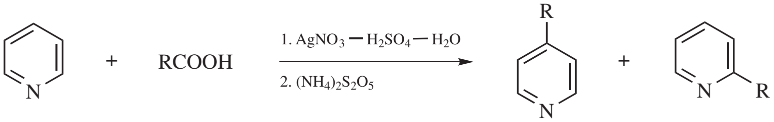
Another free-radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.[333] Yields are generally higher than in **13-27** or **14-17**. The aryl iodide may contain OH or COOH groups. The coupling reaction of iodobenzene and azulene to give a phenylazulene was reported (41% conversion and 85% yield).[334] The mechanism is similar to that of **13-27**. The aryl radicals are generated by the photolytic cleavage ArI → AR• + I•. The reaction has been applied to intramolecular arylation (analogous to the Pschorr reaction).[335] A similar reaction is photolysis of an arylthallium bis(trifluoroacetate) (**12-23**) in an aromatic solvent. Here too, an unsymmetrical biaryl is produced in good yields.[336] In this case, it is the C—Tl bond that is cleaved to give aryl radicals.

$$\text{Ar}'\text{Tl(OCOCF}_3)_2 \xrightarrow[\text{ArH}]{h\nu} \text{ArAr}'$$

14-19 Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles[337]

Alkylation or **Alkyl-de-hydrogenation**, and so on



Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.[338] The R group can be primary, secondary, or tertiary. The attacking species is R•, formed by[339]

$$2\,\text{Ag}^{+} + \text{S}_2\text{O}_8^{\,2-} \longrightarrow 2\,\text{Ag}^{2+} + 2\,\text{SO}_4^{\,2-}$$

$$\text{RCOOH} + \text{Ag}^{2+} \longrightarrow \text{RCOO}\bullet + \text{H}^{+} + \text{Ag}^{+}$$

$$\text{RCOO}\bullet \longrightarrow \text{R}\bullet + \text{CO}_2$$

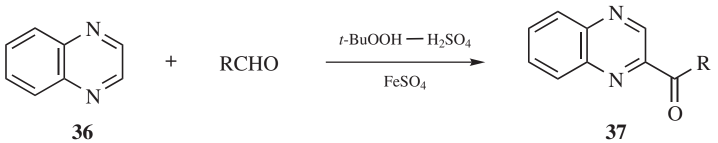
[339]Anderson, J.M.; Kochi, J.K. *J. Am. Chem. Soc.* ***1970***, *92*, 1651.

A hydroxymethyl group can be introduced (ArH → $ArCH_2OH$) by several variations of this method.[340] Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and $FeSO_4$,[341] from alkyl iodides and H_2O_2—Fe(II),[342] from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.[343]

Protonated nitrogen heterocycles, such as quinoxaline (**36**), can be acylated by treatment with an aldehyde, *tert*-butyl hydroperoxide, sulfuric acid, and ferrous sulfate, in this case giving **37**.[344]



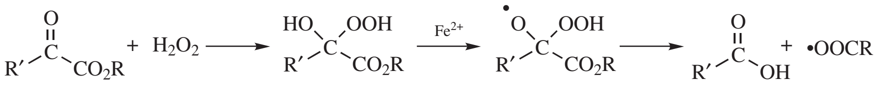
36 **37**

Photochemical alkylation of protonated quinoline occurred with $Ph_2Se(O_2Cc\text{-}C_6H_{11})_2$.[345]

Other positively charged heterocycles react as well. When *N*-fluoropyridinium triflate was treated with the enolate anion of acetone, 2-(2-oxopropyl)pyridine was formed in modest yield.[346]

These alkylation and acylation reactions are important because Friedel–Crafts alkylation and acylation (**11-11**, **11-17**) cannot be applied to most nitrogen heterocycles (see also **13-17**).

Protonated nitrogen heterocycles can be carbalkoxylated[347] by treatment with esters of α-keto acids and Fenton's reagent. Pyridine is carbalkoxylated at C-2 and C-4, for example. The attack is by •COOR radicals generated from the esters via a hydroperoxide (**38**).



38

Similarly, a carbamoyl group can be introduced[348] by the use of the radicals $H_2N{-}\overset{\displaystyle \cdot}{C}(=O)$ or $Me_2N{-}\overset{\displaystyle \cdot}{C}(=O)$ generated from formamide or DMF and H_2SO_4, H_2O_2, and $FeSO_4$ or other oxidants.

N_2 AS LEAVING GROUP[349]

In these reactions diazonium salts are cleaved to aryl radicals,[350] in most cases with the assistance of copper salts. Reactions **13-27** and **13-26** may also be regarded as belonging to this category with respect to the attacking compound. For nucleophilic substitutions of diazonium salts (see **13-20–13-23**). Removal of nitrogen and replacement with a hydrogen atom is a reduction, found in Chapter 19.

14-20 Replacement of the Diazonium Group by Chlorine or Bromine

Chloro-de-diazoniation, and so on

$$ArN_2^+ + CuCl \longrightarrow ArCl$$

Treatment of diazonium salts with cuprous chloride or bromide leads to aryl chlorides or bromides, respectively. In either case, the reaction is called the *Sandmeyer reaction.*[351] The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman reaction* (not to be confused with **11-18**). The Sandmeyer reaction is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is not known with certainty, but is believed to take the following course:[352]

$$ArN_2^+X^- + CuX \longrightarrow Ar\bullet + N_2 + CuX_2$$
$$Ar\bullet + CuX_2 \longrightarrow ArX + CuX$$

Org. Chem.* ***1969***, *34*, 710; Galli, C. *J. Chem. Soc. Perkin Trans. 2* ***1981***, 1459; ***1982***, 1139; ***1984***, 897. See also, Hanson, P.; Jones, J.R.; Gilbert, B.C.; Timms, A.W. *J. Chem. Soc. Perkin Trans. 2* ***1991***, 1009.

The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. The CuX is regenerated and is thus a true catalyst.

Aryl bromides and chlorides can be prepared from primary aromatic amines in one step by several procedures,[353] including treatment of the amine (*1*) with *tert*-butyl nitrite and anhydrous $CuCl_2$ or $CuBr_2$ at 65°C,[354] and (*2*) with *tert*-butyl thionitrite or *tert*-butyl thionitrate and $CuCl_2$ or $CuBr_2$ at room temperature.[355] These procedures are, in effect, a combination of **13-19** and the Sandmeyer reaction. A further advantage is that cooling to 0°C is not needed. A mixture of Me_3SiCl and $NaNO_2$ was used to convert aniline to chlorobenzene in a related reaction.[356]

For the preparation of fluorides and iodides from diazonium salts (see **13-32** and **13-31**).

$$ArN_2^+ + CuCN \longrightarrow ArCN$$

It is noted that the reaction of aryl diazonium salts with CuCN to give benzonitrile derivatives is also called the *Sandmeyer reaction*. It is usually conducted in neutral solution to avoid liberation of HCN.

OS **I**, 135, 136, 162, 170; **II**, 130; **III**, 185; **IV**, 160. Also see, OS **III**, 136; **IV**, 182. For the reaction with CuCN, see OS **I**, 514.

14-21 Replacement of the Diazonium Group by Nitro

Nitro-de-diazoniation

$$ArN_2^+ + NaNO_2 \xrightarrow{Cu^+} ArNO_2$$

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the Sandmeyer reaction, although, like **14-20**, it was discovered by Sandmeyer. Tetrafluoroborate (BF_4–) is often used as the negative ion since the diminished nucleophilicity avoids competition from the chloride ion. The mechanism is probably like that of **14-20**.[357] If electron-withdrawing groups are present, the catalyst is not needed; $NaNO_2$ alone gives nitro compounds in high yields.[358]

[353]For other procedures, see Brackman,W.; Smit, P.J. *Recl. Trav. Chim. Pays-Bas*, ***1966***, *85*, 857; Cadogan, J.I.G.; Roy, D.A.; Smith, D.M. *J. Chem. Soc. C* ***1966***, 1249.

An alternative procedure used electrolysis, in 60% HNO_3 to convert 1-aminonaphthalene to naphthalene.[359]

OS **II**, 225; **III**, 341.

14-22 Replacement of the Diazonium Group by Sulfur-Containing Groups

Chlorosulfo-de-diazoniation

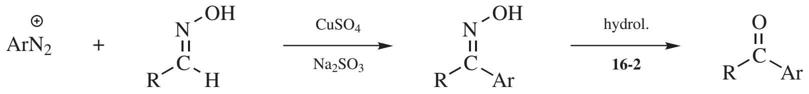
$$ArN_2^+ \; + \; SO_2 \xrightarrow[HCl]{CuCl_2} ArSO_2Cl$$

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of cupric chloride.[360] The use of $FeSO_4$ and copper metal instead of $CuCl_2$ gives sulfinic acids ($ArSO_2H$)[361] (see also, **13-21**).

OS **V**, 60; **VII**, 508.

14-23 Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids

Acyl-de-diazoniation, and so on



Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes (R = H) or ketones.[362] A copper sulfate-sodium sulfite catalyst is essential. In most cases higher yields (40–60%) are obtained when the reaction is used for aldehydes than for ketones. In another method[363] for achieving the conversion $ArN_2^+ \rightarrow ArCOR$, diazonium salts are treated with R_4Sn and CO with palladium acetate as catalyst.[364] In a different kind of reaction, silyl enol ethers of aryl ketones $Ar'C(OSiMe_3){=}CHR$ react with solid diazonium fluoroborates (ArN_2^+ BF_4^-) to give ketones (ArCHRCOAr′).[365] This is, in effect, an arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate-to-high yields by treatment of diazonium fluoroborates with carbon monoxide and palladium acetate[366] or

copper(II) chloride.[367] The mixed anhydride ArCOOCOMe is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.[368] An arylpalladium compound is probably an intermediate.[368]

OS **V**, 139.

METALS AS LEAVING GROUPS

14-24 Coupling of Grignard Reagents

De-metallo-coupling

$$2\,RMgX \xrightarrow{TlBr} RR$$

This organometallic coupling reaction is clearly related to the Wurtz coupling, discussed in **10-56**, and the coupling of other organometallic compounds is discussed in **14-25**. Grignard reagents can be coupled to give symmetrical dimers[369] by treatment with either thallium(I) bromide[370] or with a transition-metal halide, such as $CrCl_2$, $CrCl_3$, $CoCl_2$, $CoBr_2$, or $CuCl_2$.[371] The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl Grignard reagents can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with ortho substituents. Aryl Grignard reagents can also be dimerized by treatment with 1,4-dichloro-2-butene, 1,4-dichloro-2-butyne, or 2,3-dichloropropene.[372] Vinylic and alkynyl Grignard reagents can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with thionyl chloride.[373] Primary alkyl, vinylic, aryl, and benzylic Grignard reagents give symmetrical dimers in high yield (~90%) when treated with a silver(I) salt (e.g., $AgNO_3$, AgBr, $AgClO_4$) in the presence of a nitrogen-containing oxidizing agent, such as lithium nitrate, methyl nitrate, or NO_2.[374] This method has been used to close rings of four, five, and six members.[375]

The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (**12-36**), followed by its decomposition to free radicals.[376]

OS **VI**, 488.

14-25 Coupling of Other Organometallic Reagents[332]

De-metallo-coupling

$$R_2CuLi \xrightarrow[-78°C,\ THF]{O_2} RR$$

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by O_2 at −78°C in THF.[377] The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl. Other oxidizing agents, for example, nitrobenzene, can be used instead of O_2. Vinylic copper reagents dimerize on treatment with oxygen, or simply on standing at 0°C for several days or at 25°C for several hours, to yield 1,3-dienes.[378] The finding of retention of configuration for this reaction demonstrates that free-radical intermediates are not involved.

The coupling reaction of Grignard reagents was discussed in **14-24**. Lithium organoaluminates ($LiAlR_4$) are dimerized to RR by treatment with $Cu(OAc)_2$.[379] Terminal vinylic alanes (prepared by **15-17**) can be dimerized to 1,3-dienes with CuCl in THF.[380] Symmetrical 1,3-dienes can also be prepared in high yields by treatment of vinylic mercury chlorides[381] with LiCl and a rhodium catalyst[382] and by treatment of vinylic tin compounds with a palladium catalyst.[383] Arylmercuric salts are converted to biaryls by treatment with copper and a catalytic amount of $PdCl_2$.[384] Vinylic, alkynyl, and aryl tin compounds were dimerized with

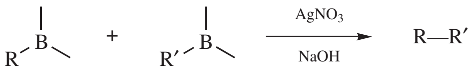
$Cu(NO_3)_2$.[385] Alkyl- and aryllithium compounds can be dimerized by transition-metal halides in a reaction similar to **14-24**.[386] Triarylbismuth compounds Ar_3Bi react with palladium(0) complexes to give biaryls ArAr.[387] Diethylzinc reacted with $Ph_2I^+ BF_4^-$ in the presence of palladium acetate, to give biphenyl.[388]

Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate-to-good yields by treatment with alkyl and vinylic dialkylcopper reagents, for example, $PhCH{=}CHHgCl + Me_2CuLi \rightarrow PhCH{=}CHMe$.[389] Unsymmetrical biaryls were prepared by treating a cyanocuprate (ArCu(CN)Li, prepared from ArLi and CuCN) with an aryllithium (Ar′Li).[390]

A radical coupling reaction has been reported, in which an aryl halide reacted with Bu_3SnH, AIBN, and benzene, followed by treatment with methyllithium to give the biaryl.[391]

14-26 Coupling of Boranes

Alkyl-de-dialkylboration



Alkylboranes can be coupled by treatment with silver nitrate and base.[392] Since alkylboranes are easily prepared from alkenes (**15-16**), this is essentially a way of coupling and reducing alkenes; in fact, alkenes can be hydroborated and coupled in the same flask. For symmetrical coupling (R = R′) yields range from 60 to 80% for terminal alkenes and from 35 to 50% for internal ones. Unsymmetrical coupling has also been carried out,[393] but with lower yields. Arylboranes react similarly, yielding biaryls.[394] The mechanism is probably of the free-radical type.

Dimerization of two vinylborane units to give a conjugated diene can be achieved by treatment of divinylchloroboranes (prepared by addition of BH_2Cl to alkynes; see **15-16**) with methylcopper. (*E*,*E*)-1,3-Dienes are prepared in high

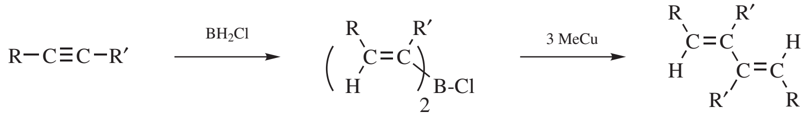
yields.[395]



In a similar reaction, symmetrical conjugated diynes RC≡C—C≡CR can be prepared by reaction of lithium dialkyldialkynylborates, Li^+ $[R'_2B(C{\equiv}CR)_2]^-$, with iodine.[396]

HALOGEN AS LEAVING GROUP

The conversion of RX to RH can occur by a free-radical mechanism but is treated at **19-53**.

SULFUR AS LEAVING GROUP

14-27 Desulfurization

Hydro-de-thio-substitution, and so on

$$RSH \xrightarrow[\text{Ni}]{H_2} RH$$

$$RSR' \xrightarrow[\text{Ni}]{H_2} RH + R'H$$

Thiols and thioethers,[397] both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.[398] The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly desulfurized, among them disulfides (RSSR),

[395]Yamamoto, Y.; Yatagai, H.; Maruyama, K.; Sonoda, A.; Murahashi, S. *J. Am. Chem. Soc.* ***1977***, *99*, 5652; *Bull. Chem. Soc. Jpn.* ***1977***, *50*, 3427. [398]For reviews, see Belen'kii, L.I., in Belen'kii, L.I. *Chemistry of Organosulfur Compounds*, Ellis Horwood, Chichester, ***1990***, pp. 193–228; Pettit, G.R.; van Tamelen, E.E. *Org. React.* ***1962***, *12*, 356; Hauptmann, H.; Walter, W.F. *Chem. Rev.* ***1962***, *62*, 347.

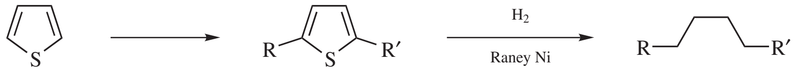
thiono esters (RCSOR′),[399] thioamides (RCDNHR′), sulfoxides, and dithioacetals. The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see **19-61**), can also give the alkene if an a hydrogen is present.[400] In most of the examples given, R can also be aryl. Other reagents[401] have also been used,[402] including samarium in acetic acid for desulfurization of vinyl sulfones.[403]

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene (see **39**), followed by reduction to the corresponding alkane.



39

Thiophenes can also be desulfurized to alkenes ($RCH_2CH{=}CHCH_2R'$ from **39**) with a nickel boride catalyst prepared from nickel(II) chloride and $NaBH_4$ in methanol.[404] It is possible to reduce just one SR group of a dithioacetal by treatment with borane–pyridine in trifluoroacetic acid or in CH_2Cl_2 in the presence of $AlCl_3$.[405] Phenyl selenides RSePh can be reduced to RH with Ph_3SnH[406] and with nickel boride.[407]

The exact mechanisms of the Raney nickel reactions are still in doubt, though they are probably of the free-radical type.[408] It has been shown that reduction of thiophene proceeds through butadiene and butene, not through 1-butanethiol or other sulfur compounds, that is, the sulfur is removed before the double bonds

14-28 Conversion of Sulfides to Organolithium Compounds

Lithio-de-phenylthio-substitution

$$\text{RSPh} \xrightarrow[\text{THF}]{\text{Li naphthalenide}} \text{RLi}$$

Sulfides can be cleaved, with a phenylthio group replaced by a lithium,[410] by treatment with lithium or lithium naphthalenide in THF.[411] Good yields have been obtained with R = primary, secondary, or tertiary alkyl, or allylic,[412] and containing groups, such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPh groups, but it is also possible to replace just one SPh from a compound with two such groups on a single carbon, to give an α-lithio sulfide.[413] The reaction has also been used to prepare α-lithio ethers and α-lithio organosilanes.[410] For some of these compounds lithium 1-(dimethylamino)naphthalenide is a better reagent than either Li or lithium naphthalenide.[414] The mechanism is presumably of the free-radical type.

CARBON AS LEAVING GROUP

14-29 Decarboxylative Dimerization: The Kolbe Reaction

De-carboxylic-coupling

$$2\,\text{RCOO}^- \xrightarrow{\text{electrolysis}} \text{R—R}$$

Electrolysis of carboxylate ions, results in decarboxylation and combination of the resulting radicals to give the coupling product R—R. This coupling

[413]See, for example, Cohen, T.; Sherbine, J.P.; Matz, J.R.; Hutchins, R.R.; McHenry, B.M.; Willey, P.R. *J. Am. Chem. Soc.* ***1984***, *106*, 3245; Ager, D.J. *J. Chem. Soc. Perkin Trans. 1* ***1986***, 183; Screttas, C.G.; Micha-Screttas, M. *J. Org. Chem.* ***1978***, *43*, 1064; ***1979***, *44*, 713.

[414]See Cohen, T.; Matz, J.R. *Synth. Commun.* ***1980***, *10*, 311.

reaction is called the *Kolbe reaction* or the *Kolbe electrosynthesis*.[415] It is used to prepare symmetrical R—R, where R is straight chained, since little or no yield is obtained when there is a branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.[415] Unsymmetrical RR′ have been made by coupling mixtures of acid salts.

A free-radical mechanism is involved:

$$\text{RCOO}^- \xrightarrow[\text{oxidation}]{\text{electrolytic}} \text{RCOO}\bullet \xrightarrow{-\text{CO}_2} \text{R}\bullet \longrightarrow \text{R–R}$$

There is much evidence[416] for this mechanism, including side products (RH, alkenes) characteristic of free-radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, see p. 1015). Other side products (ROH, RCOOR) are sometimes found, stemming from further oxidation of the radical R• to a carbocation R^+.[417]

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur:[418]

$$2\,\text{RCOO}^- + \text{CH}_2\text{=CH–CH=CH}_2 \longrightarrow \text{RCH}_2\text{CH=CHCH}_2\text{CH}_2\text{CH=CHCH}_2\text{R}$$

The radical R• adds to the conjugated system to give $RCH_2CH{=}CHCH_2\bullet$, which dimerizes. Another possible product is $RCH_2CH{=}CHCH_2R$, from coupling of the two kinds of radicals.[419]

In a nonelectrolytic reaction, which is limited to R = primary alkyl, the thiohydroxamic esters **40** give dimers when irradiated at −64°C in an argon

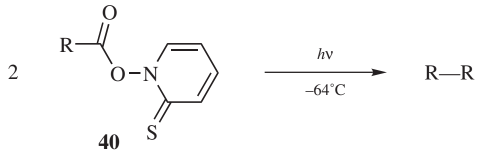
atmosphere:[420]



40

In another nonelectrolytic process, aryl acetic acids are converted to *vic*-diaryl compounds $2ArCR_2COOH \rightarrow ArCR_2CR_2Ar$ by treatment with sodium persulfate $Na_2S_2O_8$ and a catalytic amount of $AgNO_3$.[421] Photolysis of carboxylic acids in the presence of Hg_2F_2 leads to the dimeric alkane via decarboxylation.[422] Both of these reactions involve dimerization of free radicals. In still another process, electron-deficient aromatic acyl chlorides are dimerized to biaryls (2 ArCOCl → Ar—Ar) by treatment with a disilane R_3SiSiR_3 and a palladium catalyst.[423]

14-30 The Hunsdiecker Reaction

Bromo-de-carboxylation

$$RCOOAg + Br_2 \longrightarrow RBr + CO_2 + AgBr$$

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*[424] and is a way of decreasing the length of a carbon chain by one unit.[425] The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not a substituted. The group R may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine and iodine have also been used. Catalytic Hunsdiecker reactions are known.[426]

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1:1 ratio of salt/iodine gives the alkyl halide, as above.

[423]Krafft, T.E.; Rich, J.D.; McDermott, P.J. *J. Org. Chem.* ***1990***, *55*, 5430.

[424]This reaction was first reported by the Russian composer–chemist Alexander Borodin: *Liebigs Ann. Chem.* ***1861***, *119*, 121.

[425]For reviews, see Wilson, C.V. *Org. React.* ***1957***, *9*, 332; Johnson, R.G.; Ingham, R.K. *Chem. Rev.* ***1956***, *56*, 219. Also see, Naskar, D.; Chowdhury, S.; Roy, S. *Tetrahedron Lett.* ***1998***, *39*, 699.

[426]Das, J.P.; Roy, S. *J. Org. Chem.* ***2002***, *67*, 7861.

A 2:1 ratio, however, gives the ester RCOOR. This is called the *Simonini reaction* and is sometimes used to prepare carboxylic esters. The Simonini reaction can also be carried out with lead salts of acids.[427] A more convenient way to perform the Hunsdiecker reaction is by use of a mixture of the acid and mercuric oxide instead of the salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.[428]

Other methods for accomplishing the conversion RCOOH → RX are[429] (*1*) treatment of thallium(I) carboxylates[430] with bromine;[431] (*2*) treatment of carboxylic acids with lead tetraacetate and halide *ions* (Cl^-, Br^-, or I^-);[432] (*3*) reaction of the acids with lead tetraacetate and NCS, which gives tertiary and secondary chlorides in good yields, but is not good for R = primary alkyl or phenyl;[433] (*4*) treatment of thiohydroxamic esters with CCl_4, $BrCCl_3$ (which gives bromination), CHI_3, or CH_2I_2 in the presence of a radical initiator;[434] (*5*) photolysis of benzophenone oxime esters of carboxylic acids in CCl_4 ($RCON{=}CPh_2 \rightarrow RCl$).[435] Alkyl fluorides can be prepared in moderate to good yields by treating carboxylic acids RCOOH with XeF_2.[436] This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

The mechanism of the Hunsdiecker reaction is believed to be as follows:

[436] Patrick, T.B.; Johri, K.K.; White, D.H.; Bertrand, W.S.; Mokhtar, R.; Kilbourn, M.R.; Welch, M.J. *Can. J. Chem.* ***1986***, *64*, 138. For another method, see Grakauskas, V. *J. Org. Chem.* ***1969***, *34*, 2446.

The first step is not a free-radical process, and its actual mechanism is not known.[437] Compound **41** is an acyl hypohalite and is presumed to be an intermediate, though it has never been isolated from the reaction mixture. Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, see p. 942); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably RR, are consistent with a free-radical mechanism. There is evidence that the Simonini reaction involves the same mechanism as the Hunsdiecker reaction, but that the alkyl halide formed then reacts with excess RCOOAg (**10-17**) to give the ester[438] (see also **19-12**).

Vinyl carboxylic acids (conjugated acids) were shown to react with NBS and lithium acetate in aqueous acetonitrile, to give the corresponding vinyl bromide (C=C–COOH → C=C–Br), using microwave irradiation.[439] A similar reaction was reported using Na_2MoO_4, KBr and aqueous hydrogen peroxide.[440]

A related reaction reacts the sodium salt of an alkylsulfonic acid with thionyl chloride at 100°C, to give the alkyl chloride.[441]

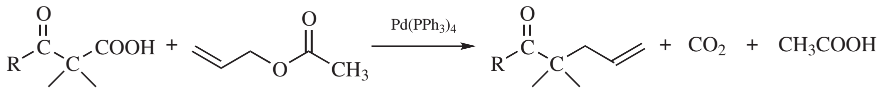
14-31 Decarboxylative Allylation

Allyl-de-carboxylation



The COOH group of a β-keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a palladium catalyst at room temperature.[442] The reaction is successful for various substituted allylic groups. The less highly substituted end of the allylic group forms the new bond. Thus, both CH_2=CHCHMeOAc and MeCH=$CHCH_2$OAc gave O=C(R)–C–CH_2CH=CHMe as the product.

[437]When Br_2 reacts with aryl R, at low temperature in inert solvents, it is possible to isolate a complex containing both Br_2 and the silver carboxylate: see Bryce-Smith, D.; Isaacs, N.S.; Tumi, S.O. *Chem. Lett.* ***1984***, 1471.

14-32 Decarbonylation of Aldehydes and Acyl Halides

Carbonyl-Extrusion

$$\text{RCHO} \xrightarrow{\text{RhCl(Ph}_3\text{P)}_3} \text{RH}$$

Aldehydes, both aliphatic and aromatic, can be decarbonylated[443] by heating with a rhodium catalyst[444] or other catalysts, such as palladium.[445] $RhCl(Ph_3P)_3$ is often called *Wilkinson's catalyst*.[446] In an older reaction, aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*tert*-butyl peroxide or other peroxides,[447] usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at ~500°C.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180°C (ArCOX → ArX).[448] This reaction has been carried out with acyl iodides,[449] bromides, and chlorides. Aliphatic acyl halides that lack an a hydrogen also give this reaction,[450] but if an α hydrogen is present, elimination takes place instead (**17-17**). Aromatic acyl cyanides give aryl cyanides (ArCOCN → ArCN).[451] Aromatic acyl chlorides and cyanides can also be decarbonylated with palladium catalysts.[452]

It is possible to decarbonylate acyl halides in another way, to give alkanes (RCOCl → RH). This is done by heating the substrate with tripropylsilane Pr_3SiH

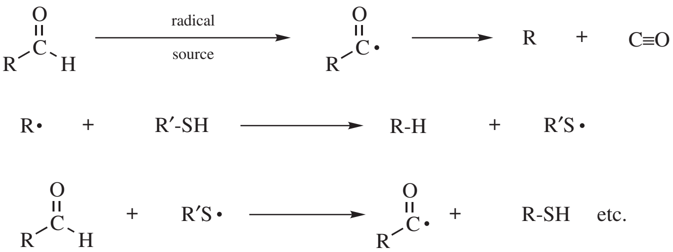
in the presence of *tert*-butyl peroxide.[453] Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl. (See also the decarbonylation ArCOCl → ArAr mentioned in **14-29**.)

The mechanism of the peroxide- or light-induced reaction seems to be as follows (in the presence of thiols):[454]



The reaction of aldehydes with Wilkinson's catalyst goes through complexes of the form **42** and **43**, which have been trapped.[455] The reaction has been shown to give retention of configuration at a chiral R;[456] and deuterium labeling demonstrates that the reaction is intramolecular: RCOD give RD.[457] Free radicals are not involved.[458] The mechanism with acyl halides appears to be more complicated.[459]

CHAPTER 15

Addition to Carbon–Carbon Multiple Bonds

There are four fundamental ways in which addition to a double or triple bond can take place. Three of these are two-step processes, with initial attack by a nucleophile, or attack upon an electrophile or a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous (concerted). Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types.

MECHANISMS

Electrophilic Addition[1]

In this mechanism, a positive species approaches the double or triple bond and in the first step forms a bond by donation of the π pair of electrons[2] to the electrophilic

[1]For a monograph, see de la Mare, P.B.D.; Bolton, R. *Electrophilic Additions to Unsaturated Systems*, 2nd ed.; Elsevier, NY, ***1982***. For reviews, see Schmid, G.H., in Patai, S. *Supplement A: The Chemistry of Double-bonded Functional Groups*, Vol. 2, pt. 1, Wiley, NY, ***1989***, pp. 679–731; Smit, W.A. *Sov. Sci. Rev. Sect. species to form a σ pair:

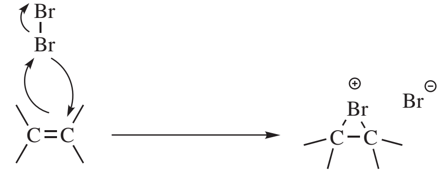
The IUPAC designation for this mechanism is $A_E + A_N$ (or $A_H + A_N$ if $Y^+ = H^+$). As in electrophilic substitution (p. 658), Y need not actually be a positive ion but can be the positive end of a dipole or an induced dipole, with the negative part breaking off either during the first step or shortly after. The second step is a combination of **1** with a species carrying an electron pair and often bearing a negative charge. This step is the same as the second step of the S_N1 mechanism. Not all electrophilic additions follow the simple mechanism given above. In many brominations it is fairly certain that **1**, if formed at all, very rapidly cyclizes to a bromonium ion (**2**):

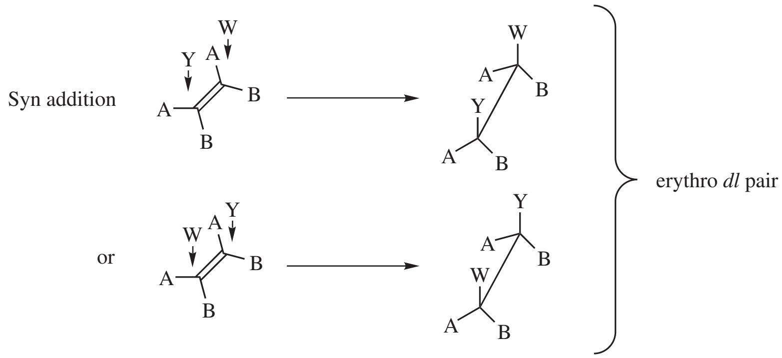


This intermediate is similar to those encountered in the neighboring-group mechanism of nucleophilic substitution (see p. 446). The attack of $\overline{\mathrm{w}}$ on an intermediate like **2** is an S_N2 step. Whether the intermediate is **1** or **2**, the mechanism is called Ad_E2 (electrophilic addition, bimolecular).

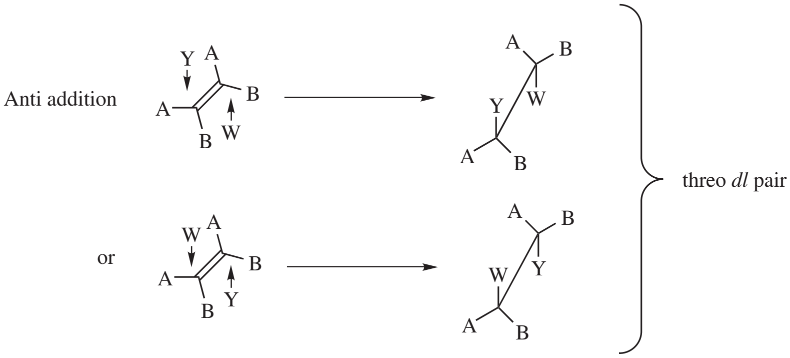
In investigating the mechanism of addition to a double bond, perhaps the most useful type of information is the stereochemistry of the reaction.[3] The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (p. 9); there are thus three possibilities. Both Y and W may enter from the same side of the plane, in which case the addition is stereospecific and syn; they may enter from opposite sides for stereospecific anti addition; or the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: YW is added to the cis and trans isomers of an alkene of the form ABC=CBA. We may use the cis alkene as an example. If the addition is syn, the product

[3]For a review of the stereochemistry of electrophilic additions to double and triple bonds, see Fahey, R.C. *Top. Stereochem.* ***1968***, *3*, 237. For a review of the synthetic uses of stereoselective additions, see Bartlett, P.A. *Tetrahedron* ***1980***, *36*, 2, pp. 3–15.

will be the erythro *dl* pair, because each carbon has a 50% chance of being attacked by Y:



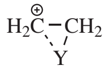
On the other hand, if the addition is anti, the threo *dl* pair will be formed:



Of course, the trans isomer will give the opposite results: the threo pair if the addition is syn and the erythro pair if it is anti. The threo and erythro isomers have different physical properties. In the special case, where Y = W (as in the addition of Br_2), the "erythro pair" is a meso compound. In addition to triple-bond compounds of the type AC≡CA, syn addition results in a cis alkene and anti addition in a trans alkene. By the definition given on p. 194 addition to triple bonds cannot be stereospecific, although it can be, and often is, stereoselective.

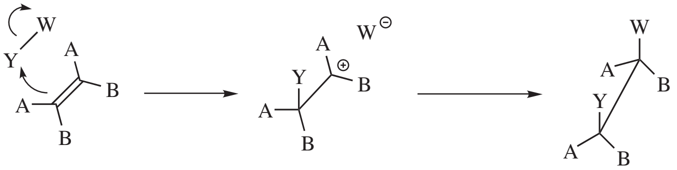
It is easily seen that in reactions involving cyclic intermediates like **2**, addition must be anti, since the second step is an S_N2 step and must occur from the back side. It is not so easy to predict the stereochemistry for reactions involving **1**. If **1** has a relatively long life, the addition should be nonstereospecific, since there will be free rotation about the single bond. On the other hand, there may be some factor that maintains the configuration, in which case W may come in from the same side or the opposite side, depending on the circumstances. For example, the positive charge might be stabilized by an attraction for Y that does not involve

a full bond (see **3**).



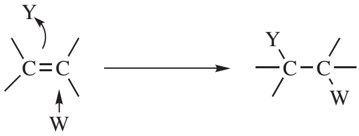
3

The second group would then come in anti. A circumstance that would favor syn addition would be the formation of an ion pair after the addition of Y:[4]



Since W is already on the same side of the plane as Y, collapse of the ion pair leads to syn addition.

Another possibility is that anti addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially simultaneous but from opposite sides:



This mechanism, called the Ad_E3 mechanism (*termolecular addition*, IUPAC A_NA_E),[5] has the disadvantage that three molecules must come together in the transition state. However, it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (p. 1478).

There is much evidence that when the attack is on Br^+ (or a carrier of it), the bromonium ion **2** is often an intermediate and the addition is anti. As long ago as 1911, McKenzie and Fischer independently showed that treatment of maleic acid with bromine gave the *dl* pair of 2,3-dibromosuccinic acid, while fumaric acid (the trans isomer) gave the meso compound.[6] Many similar experiments have been performed since with similar results. For triple bonds, stereoselective anti addition was shown even earlier. Bromination of dicarboxyacetylene gave 70%

[4]Dewar, M.J.S. *Angew. Chem. Int. Ed.* ***1964***, *3*, 245; Heasley, G.E.; Bower, T.R.; Dougharty, K.W.; Easdon, J.C.; Heasley, V.L.; Arnold, S.; Carter, T.L.; Yaeger, D.B.; Gipe, B.T.; Shellhamer, D.F. *J. Org. Chem.* ***1980***, *45*, 5150.

of the trans isomer.[7]

70% trans

There is other evidence for mechanisms involving **2**. We have already mentioned (p. 449) that bromonium ions have been isolated in stable solutions in nucleophilic substitution reactions involving bromine as a neighboring group. Such ions have also been isolated in reactions involving addition of a Br^+ species to a double bond.[8] The following is further evidence. If the two bromines approach the double bond from opposite sides, it is very unlikely that they could come from the same bromine molecule. This means that if the reaction is performed in the presence of nucleophiles, some of these will compete in the second step with the bromide liberated from the bromine. It has been found, indeed, that treatment of ethylene with bromine in the presence of chloride ions gives some 1-chloro-2-bromoethane along with the dibromoethane.[9] Similar results are found when the reaction is carried out in the presence of water (**15-40**) or of other nucleophiles.[10] *Ab initio* molecular orbital studies show that **2** is more stable than its open isomer **1** ($Y = Br$).[11] There is evidence that formation of **2** is reversible.[12]

However, a number of examples have been found where addition of bromine is not stereospecifically anti. For example, the addition of Br_2 to *cis*- and *trans*-1-phenylpropenes in CCl_4 was nonstereospecific.[13] Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent. In solvents of low dielectric constant, the addition was 90–100% anti, but with an increase in dielectric constant, the reaction became less stereospecific, until, at a dielectric constant of ~35, the addition was completely nonstereospecific.[14] Likewise in the case of triple bonds, stereoselective anti addition was found in bromi-

nation of 3-hexyne, but both cis and trans products were obtained in bromination of phenylacetylene.[15] These results indicate that a bromonium ion is not formed where the open cation can be stabilized in other ways (e.g., addition of Br^+ to 1-phenylpropene gives the ion $PhC^{\oplus}HCHBrCH_3$, which is a relatively stable benzylic cation) and that there is probably a spectrum of mechanisms between complete bromonium ion (**2**, no rotation) formation and completely open-cation (**1**, free rotation) formation, with partially bridged bromonium ions (**3**, restricted rotation) in between.[16] We have previously seen cases (e.g., p. 461) where cations require more stabilization from outside sources as they become intrinsically less stable themselves.[17] Further evidence for the open cation mechanism where aryl stabilization is present was reported in an isotope effect study of addition of Br_2 to ArCH=CHCHAr' (Ar = *p*-nitrophenyl, Ar' = *p*-tolyl). The ^{14}C isotope effect for one of the double-bond carbons (the one closer to the NO_2 group) was considerably larger than for the other one.[18]

When the π-bond of an alkene attacks Cl^+,[19] I^+,[20] and RS^+,[21] the result is similar to that when the electrophile is Br^+; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from our discussion in Chapter 10 (p. 446), iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is kinetic and spectral evidence that at least in some cases, for example, in the addition of Br_2 or ICl, the electrophile forms a π complex with the alkene before a covalent bond is formed.[22]

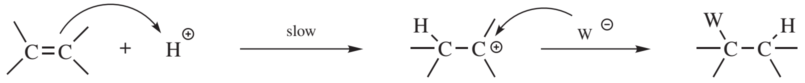
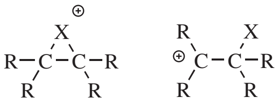
When the electrophile is a proton,[23] a cyclic intermediate is not possible, and the mechanism is the simple $A_H + A_N$ process shown before



This is an A-S_E2 mechanism (p. 525). There is a great deal of evidence[24] for it, including:

1. The reaction is general-acid, not specific-acid-catalyzed, implying rate-determining proton transfer from the acid to the double bond.[25]
2. The existence of open carbocation intermediates is supported by the contrast in the pattern of alkyl substituent effects[26] with that found in brominations, where cyclic intermediates are involved. In the latter case, substitution of alkyl groups on $H_2C{=}CH_2$ causes a cumulative rate acceleration



until all four hydrogens have been replaced by alkyl groups, because each group helps to stabilize the positive charge.[27] In addition of HX, the effect is not cumulative. Replacement of the two hydrogens on one carbon causes great rate increases (primary → secondary → tertiary carbocation), but additional substitution on the other carbon produces little or no acceleration.[28] This is evidence for open cations when a proton is the electrophile.[29]

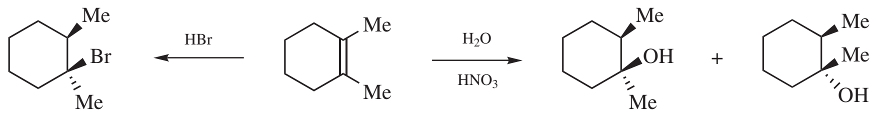
[29]A similar result (open cations) was obtained with carbocations Ar_2CH^+ as electrophiles: Mayr, H.; Pock, R. *Chem. Ber.* ***1986***, *119*, 2473.

3. Open carbocations are prone to rearrange (Chapter 18). Many rearrangements have been found to accompany additions of HX and H_2O.[30]

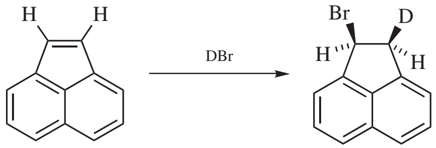
It may also be recalled that vinylic ethers react with proton donors in a similar manner (see **10-6**).

The stereochemistry of HX addition is varied. Examples are known of predominant syn, anti, and nonstereoselective addition. It was found that treatment of 1,2-dimethylcyclohexene (**4**) with HBr gave predominant anti addition,[31] while addition of water to **4** gave equal amounts of the cis and trans alcohols:[32]



4

On the other hand, addition of DBr to acenaphthylene (**5**) and to indene and 1-phenylpropene gave predominant syn addition.[33]



5

In fact, it has been shown that the stereoselectivity of HCl addition can be controlled by changing the reaction conditions. Addition of HCl to **4** in CH_2Cl_2 at −98°C gave predominantly syn addition, while in ethyl ether at 0°C, the addition was mostly anti.[34]

[30]For example, see Whitmore, F.C.; Johnston, F. *J. Am. Chem. Soc.* ***1933***, *55*, 5020; Fahey, R.C.; McPherson, C.A. *J. Am. Chem. Addition of HX to triple bonds has the same mechanism, although the intermediate in this case is a vinylic cation, **6**.[35]

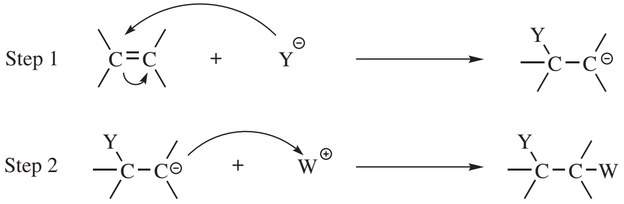
In all these cases (except for the Ad_E3 mechanism), we assumed that formation of the intermediate (**1**, **2**, or **3**) is the slow step and attack by the nucleophile on the intermediate is rapid, and this is probably true in most cases. However, some additions have been found in which the second step is rate determining.[36]

Nucleophilic Addition[37]

In the first step of nucleophilic addition, a nucleophile brings its pair of electrons to one carbon atom of the double or triple bond, creating a carbanion. The second step is combination of this carbanion with a positive species:



This mechanism is the same as the simple electrophilic one shown on p. 999 except that the charges are reversed (IUPAC $A_N + A_E$ or $A_N + A_H$). When the alkene contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, see p. $$$).

In the special case of addition of HY to a substrate of the form —C=C—Z, where Z = CHO, COR[38] (including quinones[39]), COOR, $CONH_2$, CN, NO_2, SOR,

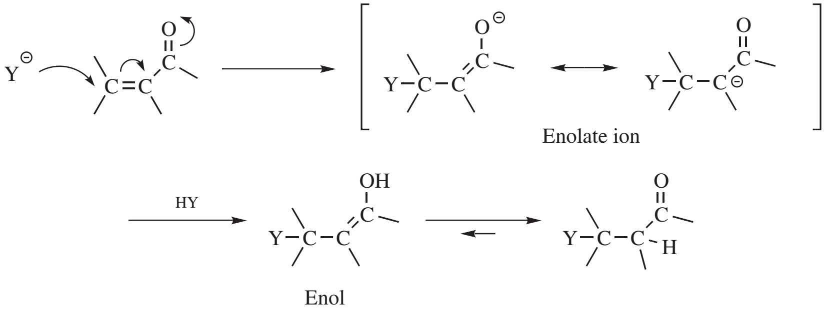
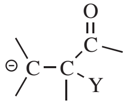
SO_2R,[40] and so on, addition nearly always follows a nucleophilic mechanism,[41] with Y^- bonding with the carbon *away* from the Z group, for example,



Protonation of the enolate ion is chiefly at the oxygen, which is more negative than the carbon, but this produces the enol, which tautomerizes (see p. 102). So although the net result of the reaction is addition to a carbon–carbon double bond, the *mechanism* is 1,4-nucleophilic addition to the C=C—C=O (or similar) system and is thus very similar to the mechanism of addition to carbon–oxygen double and similar bonds (see Chapter 16). When Z is CN or a C=O group, it is also possible for Y^- to attack at *this* carbon, and this reaction sometimes competes. When it happens, it is called 1,2-addition. 1,4-Addition to these substrates is also known as *conjugate addition*. The Y^- ion almost never attacks at the 3 position, since the resulting carbanion would have no resonance stabilization:[42]



An important substrate of this type is acrylonitrile, and 1,4-addition to it is called *cyanoethylation* because the Y is cyanoethylated:

$$H_3C{=}CH{-}CN \quad + \quad H{-}Y \quad \longrightarrow \quad Y{-}CH_2{-}CH_2{-}CV$$

With any substrate, when Y is an ion of the type $Z{-}C^{\ominus}R_2$ (Z is as defined above; R may be alkyl, aryl, hydrogen, or another Z), the reaction is called the *Michael reaction* (see **15-24**). In this book we will call all other reactions that follow this mechanism *Michael-type additions*. Systems of the type C=C—C=C—Z can give

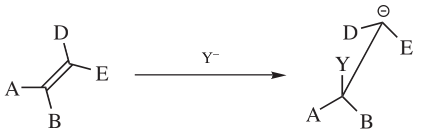
[40]For a review of vinylic sulfones, see Simpkins, N.S. *Tetrahedron* ***1990***, *46*, 6951. For a review of conjugate addition to cycloalkenyl sulfones, see Fuchs, P.L.; Braish, T.F. *Chem. Rev.* ***1986***, *86*, 903.

[41]For a review of the mechanism with these substrates, see Bernasconi, C.F. *Tetrahedron* ***1989***, *45*, 4017.

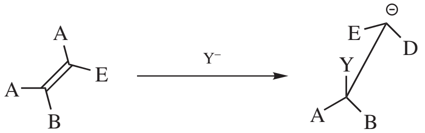
[42]For 1,8-addition to a trienone, see Barbot, F.; Kadib-Elban, A.; Miginiac, P. *J. Organomet. Chem.* ***1988***, *345*, 239.

1,2-1,4- or 1,6-addition.[43] Michael-type reactions are reversible, and compounds of the type YCH_2CH_2Z can often be decomposed to YH and $CH_2{=}CHZ$ by heating, either with or without alkali.

If the mechanism for nucleophilic addition is the simple carbanion mechanism outlined on p. 1007, the addition should be nonstereospecific, although it might well be stereoselective (see p. 194 for the distinction). For example, the (*E*) and (*Z*) forms of an alkene ABC=CDE would give **7** and **8**.



7



8

If the carbanion has even a short lifetime, **7** and **8** will assume the most favorable conformation before the attack of W. This is of course the same for both, and when W attacks, the same product will result from each. This will be one of two possible diastereomers, so the reaction will be stereoselective; but since the cis and trans isomers do not give rise to different isomers, it will not be stereospecific. Unfortunately, this prediction has not been tested on open-chain alkenes. Except for Michael-type substrates, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the cis isomer exists. In these cases the reaction has been shown to be stereoselective, with syn addition reported in some cases[44] and anti addition in others.[45] When the reaction is performed on a Michael-type substrate, C=C–Z, the hydrogen does not arrive at the carbon directly but only through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of Me_3CSD to *trans*-MeCH=CHCOOEt) predominant anti addition was found; there is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.[46] For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and

[43]However, attack at the 3 position has been reported when the 4 position contains one or two carbanion-stabilizing groups such as $SiMe_3$: Klumpp, G.W.; Mierop, A.J.C.; Vrielink, J.J.; Brugman, A.; Schakel, M. *J. Am. Chem. Soc.* ***1985***, *107*, 6740.

anti,[47] although syn addition[48] and nonstereoselective addition[49] have also been reported.

Free-Radical Addition

The mechanism of free-radical addition[50] follows the pattern discussed in Chapter 14 (pp. 934–939). The method of principal component analysis has been used to analyze polar and enthalpic effect in radical addition reactions.[51] A radical is generated by

$$\text{YW} \xrightarrow[\text{dissociation}]{h\nu \text{ or spontaneous}} \text{Y}\bullet + \text{W}\bullet$$

or

$$\text{R}\bullet \ \text{(from some other source)} + \text{YW} \longrightarrow \text{RW} + \text{Y}\bullet$$

Propagation then occurs by

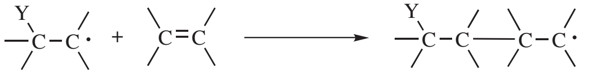
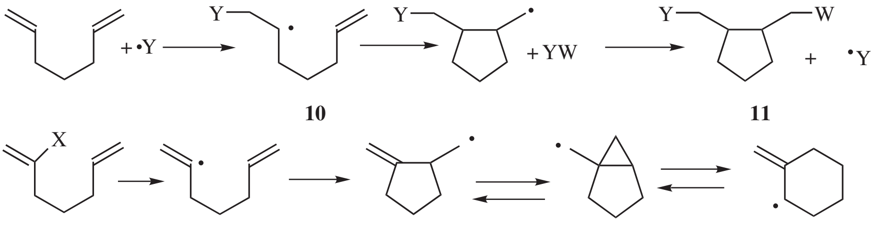
Step 2 is an abstraction (an atom transfer), so W is nearly always univalent, either hydrogen or halogen (p. 943). Termination of the chain can occur in any of the ways discussed in Chapter 14. If **9** adds to another alkene molecule,



9

a dimer is formed. This can add to still another, and chains, long or short, may be built up. This is the mechanism of free-radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free-radical addition reactions.

When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical (**10**) can add intramolecularly to the other bond, leading to a cyclic product (**11**).[52] When the radical is generated from an precursor that gives vinyl radical **12**, however, cyclization leads to **13**, which is in equilibrium with cyclopropylcarbinyl radical (**14**) via a 5-exo-trig reaction.[53] A 6-endo-trig reaction leads to **15**, but unless there are perturbing substituent effects, however, cyclopropanation should be the major process.



10 **11**

12 **13** **14** **15**

Radicals of the type **10**, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed in these reactions (see p. 1021).

The free-radical addition mechanism just outlined predicts that the addition should be non-stereospecific, at least if **9** has any, but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed for nucleophilic addition on p. 1007. Not all free-radical additions have been found to be selective, but many are. For example, addition of HBr to 1-bromocyclohexene is regioselective in that it gave only *cis*-1,2-dibromocyclohexane

[52]For reviews of these and other free-radical cyclization reactions, see RajanBabu, T.V. *Acc. Chem. Res.* ***1991***, *24*, 139; Beckwith, A.L.J. *Rev. Chem. and none of the trans isomer (anti addition),[54] and propyne (at −78 to −60°C) gave only *cis*-1-bromopropene (anti addition), making it stereoselective.[55] However, stereospecificity has been found only in a few cases. Selectivity was observed in radical cyclization reactions of functionalized alkenes, which proceeded via a trans-ring closure.[56] The most important case is probably addition of HBr to 2- bromo-2-butene under free-radical conditions at −80°C. Under these conditions, the cis isomer gave 92% of the meso product, while the trans isomer gave mostly the *dl* pair.[57] This stereospecificity disappeared at room temperature, where both alkenes gave the same mixture of products (~78% of the *dl* pair and 22% of the meso compound), so the addition was still stereoselective but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through the formation of a bridged bromine radical, of the type mentioned on p. 942:

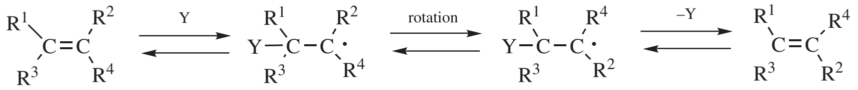
This species is similar to the bromonium ion that is responsible for stereospecific anti addition in the electrophilic mechanism. Further evidence for the existence of such bridged radicals was obtained by addition of Br• to alkenes at 77 K. The ESR spectra of the resulting species were consistent with bridged structures.[58]

For many radicals, step 1 (C=C + Y• → •C—C—Y) is reversible. In such cases, free radicals can cause cis → trans isomerization of a double bond by the pathway[59]



Cyclic Mechanisms

There are some addition reactions where the initial attack is not at one carbon of the double bond, but both carbons are attacked simultaneously. Some of these are

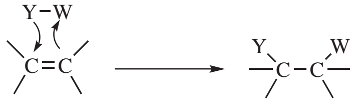
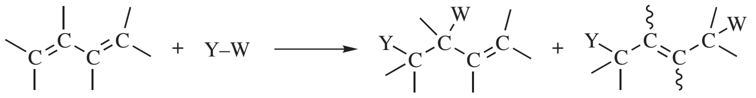
four-center mechanisms, which follow this pattern:



In others, there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be syn. The most important reaction of this type is the Diels–Alder reaction (**15-60**).

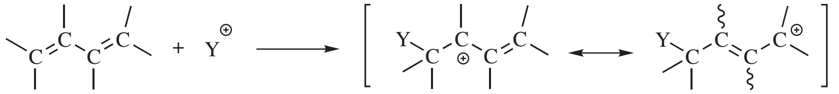
Addition to Conjugated Systems

When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product (**16**) is often obtained, but in most cases there is also a 1,4-addition product (**17**), often in larger yield:[60]

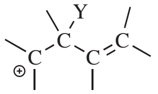


16 **17**

If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack on Y^+ is a resonance hybrid, with partial positive charges at the 2 and 4 positions:



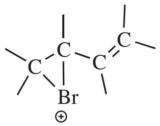
W^- may then attack either position. The original attack of Y^+ is always at the end of the conjugated system because an attack at a middle carbon would give a cation unstabilized by resonance:

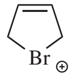


In the case of electrophiles like Br^+, which can form cyclic intermediates, both 1,2- and 1,4-addition products can be rationalized as stemming from an intermediate like **18**. Direct nucleophilic attack by W^- would give the 1,2-product, while the 1,4-product could be formed by attack at the 4 position, by an S_N2'-type mechanism (see p. 470). Intermediates like **19** have been postulated, but ruled out for Br and Cl

[60]For a review of electrophilic addition to conjugated dienes, see Khristov, V.Kh.; Angelov, Kh.M.; Petrov, A.A. *Russ. Chem. Rev.* ***1991***, *60*, 39.

by the observation that chlorination

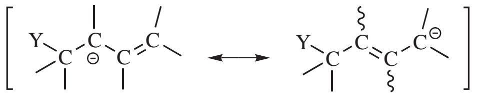


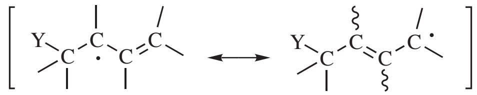


18 **19**

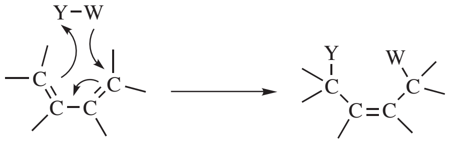
or bromination of butadiene gives trans 1,4-products.[61] If an ion like **19** were the intermediate, the 1,4-products would have to have the cis configuration.

In most cases, more 1,4- than 1,2-addition product is obtained. This may be a consequence of thermodynamic control of products, as against kinetic. In most cases, under the reaction conditions, **16** is converted to a mixture of **16** and **17** which is richer in **17**. That is, either isomer gives the same mixture of both, which contains more **17**. It was found that at low temperatures, butadiene and HCl gave only 20–25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.[62] 1,2-Addition predominated over 1,4- in the reaction between DCl and 1,3-pentadiene, where the intermediate was the symmetrical (except for the D label) $H_3CHC\overset{\oplus}{\overline{-CH-}}CHCH_2D$[63] Ion pairs were invoked to explain this result, since a free ion would be expected to be attacked by Cl^- equally well at both positions, except for the very small isotope effect.





Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case, there is competition between 1,2- and 1,4-addition. In the case of nucleophilic or free-radical attack,[64] the intermediates are resonance hybrids and behave like the intermediate from electrophilic attack. Dienes can give 1,4-addition by a cyclic mechanism in this way:



[61]Mislow, K. *J. Am. Chem. Soc.* ***1953***, *75*, 2512.

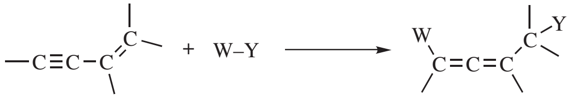
[64]For a review of free-radical addition to conjugated dienes, see Afanas'ev, I.B.; Samokhvalov, G.I. *Russ. Chem. Rev.* ***1969***, *38*, 318.

Other conjugated systems, including trienes, enynes, diynes, and so on, have been studied much less, but behave similarly. 1,4-Addition to enynes is an important way of making allenes:



Radical addition to conjugated systems is an important part of chain propagation reactions. The rate constants for addition of cyclohexyl radical to conjugated amides have been measured, and shown to be faster than addition to styrene.[65] In additions to $RCH{=}C(CN)_2$ systems, where the R group has a chiral center, the Felkin–Ahn rule (p. 169) is followed and the reaction proceeds with high selectivity.[66] Addition of some radicals, such as $(Me_3Si)_3Si\bullet$, is reversible and this can lead to poor selectivity or isomerization.[67]

ORIENTATION AND REACTIVITY

Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1 and 15.2.[68] As a further illustration it may be mentioned that the reactivity toward electrophilic addition of a group of alkenes increased in the order $CCl_3CH{=}CH_2 < Cl_2CHCH{=}CH_2 < ClCH_2CH{=}CH_2 < CH_3CH_2{=}CH_2$.[69] For nucleophilic addition the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being $F_2C{=}CF_2$[70] and $(NC)_2C{=}C(CN)_2$.[71] The effect of substituents is so great that it is possible to make the statement that *simple alkenes do not react by the nucleophilic mechanism, and polyhalo or polycyano alkenes do not generally react by the electrophilic mechanism.*[72]

[72]Such reactions can take place under severe conditions. For example, electrophilic addition could be accomplished with $F_2C{=}CHF$ in super acid solutions [Olah, G.A.; Mo, Y.K. *J. Org. Chem.* ***1972***, *37*, 1028] although $F_2C{=}CF_2$ did not react under these conditions. For reviews of electrophilic additions to fluoroalkenes, see Belen'kii, G.G.; German, L.S. *Sov. Sci. Rev. TABLE 15.1. Relative Reactivity of Some Alkenes Toward Bromine in Acetic Acid at 24°C[68]

Alkene	Relative Rate
$PhCH{=}CH_2$	Very fast
$PhCH{=}CHPh$	18
$CH_2{=}CHCH_2Cl$	1.6
$CH_2{=}CHCH_2Br$	1.0
$PhCH{=}CHBr$	0.11
$CH_2{=}CHBr$	0.0011

TABLE 15.2. Relative Reactivity of Some Alkenes Toward Bromine in Methanol[68]

Alkene	Relative Rate
$CH_2{=}CH_2$	3.0×10^1
$CH_3CH_2CH{=}CH_2$	$2/9 \times 10^3$
cis-$CH_3CH_2CH{=}CHCH_3$	1.3×10^5
$(CH_3)_2C{=}C(CH_3)_2$	2.8×10^7

There are some reagents that attack only as nucleophiles, for example, ammonia, and these add only to substrates susceptible to nucleophilic attack. Other reagents attack only as electrophiles, and, for example, $F_2C{=}CF_2$ does not react with these. In still other cases, the same reagent reacts with a simple alkene by the electrophilic mechanism and with a polyhalo alkene by a nucleophilic mechanism. For example, Cl_2 and HF are normally electrophilic reagents, but it has been shown that Cl_2 adds to $(N{\equiv}C)_2C{=}CHC{\equiv}N$ with initial attack by Cl^-[73] and that HF adds to $F_2C{=}CClF$ with initial attack by F^-.[74] Compounds that have a double bond conjugated with a Z group (as defined on p. 1007) nearly always react by a nucleophilic mechanism.[75] These are actually 1,4-additions, as discussed on p. 1008. A number of studies have been made of the relative activating abilities of various Z groups.[76] On the basis of these studies, the following order of decreasing activating ability has been suggested: Z = NO_2, COAr, CHO, COR, SO_2Ar, CN, COOR, SOAr, $CONH_2$, CONHR.[77]

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of

[75]For a review of electrophilic reactions of such compounds, see Müllen, K.; Wolf, P., in Patai, S.; Rappoport, Z. *The Chemistry of Enones*, pt. 1, Wiley, NY, ***1989***, pp. 513–558.

[76]See, for example, Friedman, M.; Wall, J.S. *J. Org. Chem.* ***1966***, *31*, 2888; Ring, R.N.; Tesoro, G.C.; Moore, D.R. *J. Org. Chem.* ***1967***, *32*, 1091.

[77]Shenhav, H.; Rappoport, Z.; Patai, S. *J. Chem. Soc. B* ***1970***, 469.

the double bond. Addition of electrophilic radicals to electron rich alkenes has been reported,[78] so the reaction is possible in some cases. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.[79] There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and yet triple bonds are *less* subject to attack at an electrophilic site and *more* subject to nucleophilic attack than double bonds.[80] This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.[81] In fact, all reagents that form bridged intermediates like **2** react faster with double than with triple bonds. On the other hand, addition of electrophilic H^+ (acid-catalyzed hydration, **15-3**; addition of hydrogen halides, **15-2**) takes place at about the same rates for alkenes as for corresponding alkynes.[82] Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene $PhCH{=}CH_2$ was brominated 3000 times faster than $PhC{\equiv}CH$, the addition of a second phenyl group ($PhCH{=}CHPh$ versus $PhC{\equiv}CPh$) lowered the rate ratio to about 250.[83] In the case of *trans*-$MeOOCCH{=}CHCOOMe$ versus $MeOOCC{\equiv}CCOOMe$, the triple bond compound was actually brominated faster.[84]

As mentioned, it is true that in general triple bonds are more susceptible to nucleophilic and less to attack on an electrophilic site than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly because of the smaller carbon–carbon distance; it is thus harder for an attacking electrophile to pull out a pair. There is evidence from far-UV spectra to support this conclusion.[85] Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π^* orbital of bent alkynes (e.g., cyclooctyne) has a lower energy than the π^* orbital of alkenes, and it has been suggested[86] that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile. Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**20**) are more strained than the corresponding **21** and furthermore are antiaromatic systems

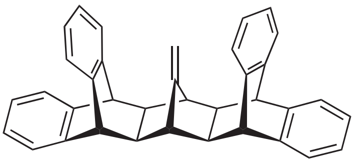
(see p. 73), which **21** are not. This may be a reason why electrophilic addition by such electrophiles as Br, I, SR, and so on, is slower for triple than for double bonds.[87] As might be expected, triple bonds connected to a Z group (C≡C–Z) undergo nucleophilic addition especially well.[88]

20 **21**

Although alkyl groups in general increase the rates of electrophilic addition, we have already mentioned (p. 1005) that there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.[89] Where the second step is rate determining [e.g., oxymercuration (**15-3**), hydroboration (**15-17**)], steric effects are important.[88]

Free-radical additions can occur with any type of substrate. The determining factor is the presence of a free-radical attacking species. Some reagents (e.g., HBr, RSH) attack by ionic mechanisms if no initiator is present, but in the presence of a free-radical initiator, the mechanism changes and the addition is of the free-radical type. Nucleophilic radicals (see p. 938) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.[90] However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,[91] which is contrary to what might have been expected.[92]



22

[87]Nevertheless, bridged ions **15** have been implicated in some additions to triple bonds. See, for example, Pincock, J.A.; Yates, K. *Can. J. Chem.* ***1970***, *48*, 3332; Mauger, E.; Berliner, E. *J. Am. Chem. Soc.* ***1972***, *94*, 194; Bassi, P.; Tonellato, U. *J. Chem. Soc. Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon **22**, in which the double bond is entombed between the benzene rings, does not react with Br_2, H_2SO_4, O_3, BH_3, **:**CBr_2, or other reagents that react with most double bonds.[93] A similarly inactive compound is tetra-*tert*-butylallene $(t\text{-Bu})_2C{=}C{=}C(t\text{-Bu})_2$, which is inert to Br_2, Cl_2, O_3, and catalytic hydrogenation.[94]

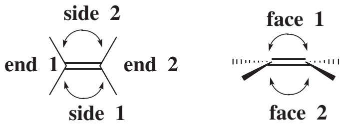
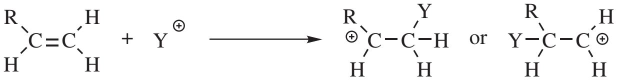
Orientation

When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises: Which side of the reagent goes to which side of the double or triple bond? The terms side and face are arbitrary, and a simple guide is shown to help understand the arguments used here. For electrophilic attack, the answer is given by

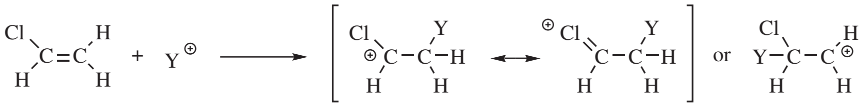


Markovnikov's rule: The positive portion of the reagent goes to the side of the double or triple bond that has more hydrogens.[95] A number of explanations have been suggested for this regioselectivity, but the most probable is that Y^+ adds to that side that will give the more stable carbocation. This premise has been examined by core electron spectroscopy and by theoretical analysis.[96] Thus, when an alkyl group is present, secondary carbocations are more stable than primary:



More stable

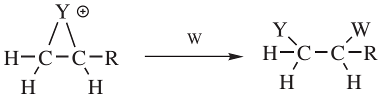
We may ask: Why does Y^+ add to give the more stable carbocation? As in the similar case of electrophilic aromatic substitution (p. 658), we invoke the Hammond postulate and say that the lower energy carbocation is preceded by the lower energy transition state. Markovnikov's rule also applies for halogen substituents because the halogen stabilizes the carbocation by resonance:



More stable

[93]Butler, D.N.; Gupt, I.; Ng, W.W.; Nyburg, S.C. *J. Chem. Soc., Chem. Commun.* ***1980***, 596.
[94]Bolze, R.; Eierdanz, H.; Schlüter, K.; Massa, W.; Grahn, W.; Berndt, A. *Angew. Chem. Int. Ed.* ***1982***, *21*, 924.
[95]For discussions of Markovnikov's rule, see Isenberg, N.; Grdinic, M. *J. Chem. Educ.* ***1969***, *46*, 601; Grdinic, M.; Isenberg, N. *Intra-Sci. Chem. Rep.*, ***1970***, *4*, 145–162.
[96]Sæthre, L.J.; Thomas, T.D.; Svensson, S. *J. Chem. Soc. Perkin Trans. 2*, ***1997***, 749.

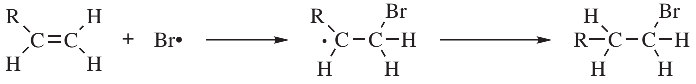
Markovnikov's rule is also usually followed where bromonium ions or other three-membered rings are intermediates.[97] This means that in these cases attack by W must resemble the S_N1 rather than the S_N2 mechanism (see p. 517), although the overall stereospecific anti addition in these reactions means that the nucleophilic substitution step is taking place with inversion of configuration.



Alkenes containing strong electron-withdrawing groups may violate Markovnikov's rule. For example, attack at the Markovnikov position of Me_3N^+—CH=CH_2 would give an ion with positive charges on adjacent atoms. The compound CF_3CH=CH_2 has been reported to give electrophilic addition with acids in an anti-Markovnikov direction, but it has been shown[98] that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently anti-Markovnikov products are formed by other pathways. Molecular electrostatic potentials for the π-region of substituted alkenes were studied, with electron donating and withdrawing substituents (based on the increase or decrease in the negative character of V_{min}-most negative-valued point), and plots of V_{min} shows a good linear correlation with the Hammett σρ constants, suggesting similar substituent electronic effects for substituted ethylenes and substituted benzenes.[99]

For nucleophilic addition the direction of attack has been studied very little, except for Michael-type addition, with compounds of the type C=C—Z. Here the negative part of the reagent almost always attacks regioselectively at the carbon that does not carry the Z (see p. 1008).

In free-radical addition[100] the main effect seems to be steric.[101] All substrates CH_2=CHX preferentially react at the CH_2, regardless of the identity of X or of the radical. With a reagent such as HBr, this means that the addition is anti-Markovnikov:



Preferentially formed intermediate

Product

[97]This has been graphically demonstrated by direct treatment of stabilized bromonium ions by nucleophiles: Dubois, J.E.; Chrétien, J.R. *J. Am. Chem. Soc.* ***1978***, *100*, 3506.

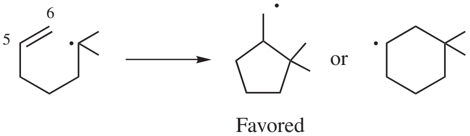
[98]Myhre, P.C.; Andrews, G.D. *J. Am. Chem. Soc.* ***1970***, *92*, 7595, 7596. See also, Newton, T.A. *J. Chem. Educ.* ***1987***, *64*, 531.

[99]Suresh, C.H.; Koga, N.; Gadre, S.R. *J. Org. Chem.* ***2001***, *66*, 6883.

[100]For reviews of orientation in free-radical additions, see Tedder, J.M.; Walton, J.C. *Tetrahedron* ***1980***, *36*, 701; *Adv. Phys. Org. Chem.* ***1978***, *16*, 51; *Acc. Chem. Res.* ***1976***, *9*, 183. See also, Giese, B. *Rev. Chem. Intermed.* ***1986***, *7*, 3; Tedder, J.M. *J. Chem. Educ.* ***1984***, *61*, 237.

[101]See, however, Riemenschneider, K.; Bartels, H.M.; Dornow, R.; Drechsel-Grau, E.; Eichel, W.; Luthe, H.; Matter, Y.M.; Michaelis, W.; Boldt, P. *J. Org. Chem.* ***1987***, *52*, 205; Gleicher, G.J.; Mahiou, B.; Aretakis, A.J. *J. Org. Chem.* ***1989***, *54*, 308.

Thus the observed orientation in both kinds of HBr addition (Markovnikov electrophilic and anti-Markovnikov free radical) is caused by formation of the secondary intermediate. In the electrophilic case it forms because it is more stable than the primary; in the free-radical case because it is sterically preferred. The stability order of the free-radical intermediates is also usually in the same direction: 3° > 2° > 1° (p. 272), but this factor is apparently less important than the steric factor. Internal alkenes with no groups present to stabilize the radical usually give an ~1:1 mixture via 5-exo–trig and 6-endo–trig (see Badwin's rules p. $$$) reactions.



Favored

In *intramolecular* additions of radicals containing a 5,6 double bond,[52] both five- and six-membered rings can be formed, but in most cases[102] the five-membered rings are greatly preferred kinetically, even (as in the case shown) where five-membered ring closure means generating a primary radical and six-membered ring closure a secondary radical. This phenomenon may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.[103] Similar behavior is found when the double bond is in other positions (from the 3,4 to the 7,8 position). In each case, the smaller ring (exo–trig addition) is preferred to the larger (endo–trig addition)[104] (see the Baldwin rules, p. 305). However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the six-membered ring is generally favored.[105]

For conjugated dienes, attack by a positive ion, a negative ion, or a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more stable ion is formed. For example, isoprene ($CH_2{=}CMeCH{=}CH_2$), treated with HCl gives only $Me_2CClCH{=}CH_2$ and $Me_2C{=}CHCH_2Cl$, with none of the product arising from attack at the other end. $PhCH{=}CHCH{=}CH_2$ gives only $PhCH{=}CHCHClCH_3$ since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack by H^+ at an end of the conjugated system.

When allenes attack electrophilic reagents,[106] Markovnikov's rule would predict that the formation of the new bond should be at the end of the system, since there are no hydrogens in the middle. Reaction at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect the three *p* orbitals must be parallel, and it requires a rotation about the C—C bond for this to happen.[107] Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (p. 148). Probably because of this, attack on the unsubstituted $CH_2{=}C{=}CH_2$ is most often at the end carbon, to give a vinylic cation, although center attack has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, attack at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form $RCH{=}C{=}CH_2$ are still attacked most often at the end, but with RCH=C=CHR' center attack is more prevalent. Tetramethylallene is also attacked predominantly at the center carbon.[108] Free radicals[109] attack allenes most often at the end,[110] although attack at the middle has also been reported.[111] As with electrophilic attack and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, as with electrophilic attack, the presence of alkyl groups increases the extent of attack by a radical at the middle carbon.[112]

Stereochemical Orientation

It has already been pointed out that some additions are syn, with both groups, approaching from the same side, and that others are anti, with the groups approaching from opposite sides of the double or triple bond. For cyclic compounds steric orientation must be considered. In syn addition to an unsymmetrical cyclic alkene,

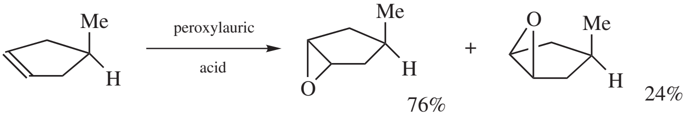
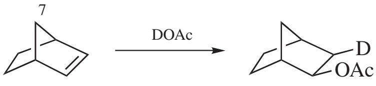
the two groups can come in from the more- or from the less-hindered face of the double bond. The rule is that syn addition is usually, although not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered and 24% from the more-hindered face.[113]

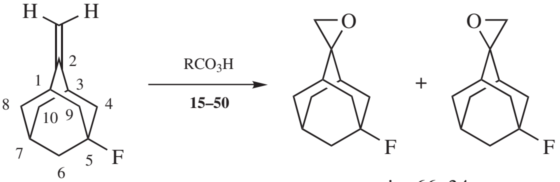


In anti addition to a cyclic substrate, the initial attack on the electrophile is also from the less-hindered face. However, many (although not all) electrophilic additions to norbornene and similar strained bicycloalkenes are syn additions.[114] In these cases reaction is always from the exo side, as in formation of **23**,[115]



23

unless the exo side is blocked by substituents in the 7 position, in which case endo attack may predominate; for example, 7,7-dimethylnorbornene undergoes syn–endo epoxidation (**15-50**) and hydroboration[116] (**15-16**). However, addition of DCl and F_3CCOOD to, and oxymercuration (**15-2**) of, 7,7-dimethylnorbornene proceeds syn–exo in spite of the methyl groups in the 7 position.[117] Similarly, free-radical additions to norbornene and similar molecules are often syn–exo, although anti additions and endo attacks are also known.[118]



ratio 66:34

24 **25** **26**

Electronic effects can also play a part in determining which face reacts preferentially with the electrophilic species. In the adamantane derivative **24**, steric

effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene reactions (**15-64**), and hydroboration (**15-16**) all predominantly take place from the face that is syn to the electron-withdrawing fluorine.[119] In the case shown, about twice as much **25** was formed, compared to **26**. Similar results have been obtained on other substrates:[120] groups that are electron withdrawing by the field effect ($-I$) direct attack from the syn face; $+I$ groups from the anti face, for both electrophilic and nucleophilic attack. These results are attributed[121] to hyperconjugation: For the adamantane case, there is overlap between the σ^* orbital of the newly forming bond (between the attacking species and C-2 in **24**) and the filled σ orbitals of the C_α—C_β bonds on the opposite side. This is called the *Cieplak effect*. The $LiAlH_4$ reduction of 2-axial methyl or methoxy cyclohexanones supports Cieplak's proposal.[122] In addition reactions of methanol to norbornanones, however, little evidence was found to support the Cieplak effect.[123] The four possible bonds are C-3–C-4 and C-1–C-9 on the syn side and C-3–C-10 and C-1–C-8 on the anti side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1–C-8 and C-3–C-10 bonds are more electron rich, and the group comes in on the face syn to the F.

It has been mentioned that additions of Br_2 and HOBr are often anti because of formation of bromonium ions and that free-radical addition of HBr is also anti. When the substrate in any of these additions is a cyclohexene, the addition is not only anti but the initially formed product is conformationally specific too, being mostly diaxial.[124] This is so because diaxial opening of the three-membered ring preserves a maximum coplanarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.[125] However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free-radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial reaction with the radical is also usually from the axial direction,[126] resulting in a diaxial initial product if the overall addition is anti. The direction from which unsymmetrical radicals react has also been studied.[127] For example, when the radical **27** adds

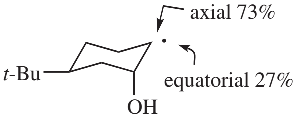
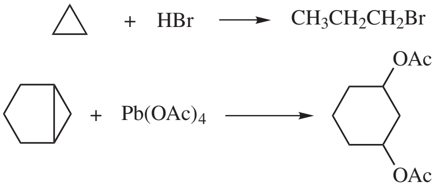
to a double bond it preferentially does so anti to the OH group, leading to a diaxial trans product.[125]



27

Addition to Cyclopropane Rings[128]

We have previously seen (p. 218) that in some respects, cyclopropane rings resemble double bonds.[129] It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double-bond compounds, resulting in the opening of the three-membered rings, as in the two examples shown where reaction numbers relating the reaction to alkene chemistry are in parentheses.

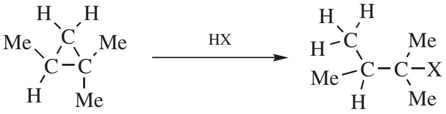


(**15-2**)

(**15-47**) Ref. [130]

Other examples are discussed at **15-3**, **15-15**, and **15-63**.

Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves attack on an electrophile.[131] For substituted cyclopropanes, these reactions usually follow Markovnikov's rule, although exceptions are known and the degree of regioselectivity is often small. The application of Markovnikov's rule to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.[132] The rule predicts that the electrophile (in this case H^+) goes to the carbon



[128]For a review, see Charton, M., in Zabicky, J. *The Chemistry of Alkenes*, Vol 2., Wiley, NY, ***1970***, pp. 569–592. with the most hydrogens and the nucleophile goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon). The stereochemistry of the reaction can be investigated at two positions the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,[133] 100% inversion,[134] and with mixtures of retention and inversion.[135] At the carbon that becomes connected to the nucleophile the result is usually inversion, although retention has also been found,[136] and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

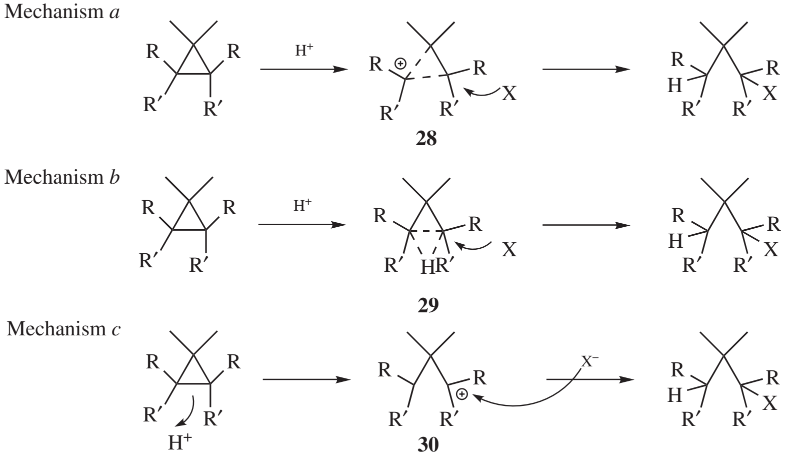
At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for attack by HX, but analogous mechanisms can be written for other electrophiles).



Mechanism *a* involves a corner-protonated cyclopropane[137] (**28**); we have already seen examples of such ions in the 2-norbornyl and 7-norbornenyl cations (pp. 453, 460). Mechanism *b* involves an edge-protonated cyclopropane (**29**). Mechanism *c*

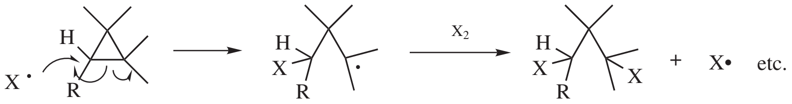
[137]For reviews of protonated cyclopropanes, see Collins, C.J. *Chem. Rev.* ***1969***, *69*, 543; Lee, C.C. *Prog. Phys. Org. Chem.* ***1970***, *7*, 129.

consists of a one-step S_E2-type attack on H^+ to give the classical cation **30**, which then reacts with the nucleophile. Although the three mechanisms as we have drawn them show retention of configuration at the carbon that becomes attached to the proton, mechanisms *a* and *c* at least can also result in inversion at this carbon. Unfortunately, the evidence on hand at present does not allow us unequivocally to select any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for mechanism *b* with the electrophiles Br^+ and Cl^+;[138] and for mechanism *a* with D^+ and Hg^{2+}.[139] *Ab initio* studies show that the corner-protonated **28** is slightly more stable (~1.4 kcal mol^{-1}, 6 kJ mol^{-1}) than the edge-protonated **29**.[140] There is some evidence against mechanism *c*.[141]

Free-radical additions to cyclopropanes have been studied much less, but it is known that Br_2 and Cl_2 add to cyclopropanes by a free-radical mechanism in the presence of UV light. The addition follows Markovnikov's rule, with the initial radical reacting at the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.[142] A mechanism that accounts for this behavior is[143]



In some cases, conjugate addition has been performed on systems where a double bond is "conjugated" with a cyclopropyl ring. An example is the formation of **31**.[144]

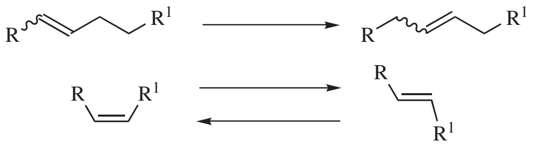
REACTIONS

Reactions are classified by type of reagent. Isomerization of double and triple bonds is followed by examination of all reactions, where hydrogen adds to one side of the double or triple bond.

ISOMERIZATION OF DOUBLE AND TRIPLE BONDS

15-1 Isomerization



There are several reagents that lead to isomerization of a double bond to form a new alkene. In general, there is an energetic preference of an α,β- versus. β,γ-double bond.[145] Transition metals have been used to induce isomerization of alkenes. Allylic arenes (Ar-$CH_2CH{=}CH_2$) have been converted to the corresponding (*Z*-)1-propenyl arene (Ar-CH=CHMe using a ruthenium catalyst[146] or a polymer-supported iridium catalyst.[147] Allyl decyl ether ($CH_2{=}CHCH_2OC_{10}H_{21}$) was isomerized to 1-decyloxy-1-propene ($CH_3CH{=}CHOC_{10}H_{21}$) by treatment with $NaHFe(CO)_4$.[148] Double-bond migration has been observed in sulfide photo-irradiation, induced by singlet oxygen.[149] *N*-Acyl allylamine can be isomerized to the *N*-acyl enamine by heating with a ruthenium catalyst.[150] Many of these reactions were discussed in **12-2**.

For conjugated carbonyl compounds that have a hydrogen atom at the γ-position (C-4), it is possible to move a double bond *out* of conjugation. Photolysis of conjugated esters, at −40°C in the presence of *N,N*- dimethylaminoethanol, gave the nonconjugated ester.[151] Heating an *N*-allylic amide (*N*-C—C=C) with $Fe(CO)_5$, neat, gave the enamide (*N*-C=C—C).[152]

Isomerization of (*E/Z*) isomers is another important transformation.[153] Isomerization of (*E*)- and (*Z*)-conjugated amides is effected photochemically[154]

(photoisomerization[155]). There is a rather high energy barrier for the excited state required for (*E/Z*) isomerization.[156] Isomerization of the C=C units in dienes is also induced photochemically.[157] Isomerization of cyclic alkenes is more difficult but cyclooctene is isomerized photochemically.[158] The photosensitized cis–trans isomerization of 1,2-dichloroethylenes have been reported,[159] and also the photoisomerization of cis/trans cyclooctene.[160] Radical-induced (*E/Z*) isomerization is known.[161]

Conjugated aldehydes have been isomerized using thiourea in DMF.[162] A 1:1 mixture of cis/trans styrene derivatives was isomerized to a 90% yield of the trans styrene derivatives was reported using a palladium catalyst.[163] Thermal cis–trans isomerization of 1,3-diphenyltriazenes has been reported, in aqueous solution.[164]

REACTIONS IN WHICH HYDROGEN ADDS TO ONE SIDE

A. Halogen on the Other Side

15-2 Addition of Hydrogen Halides

Hydro-halo-addition

Any of the four hydrogen halides can be added to double bonds.[165] HI, HBr, and HF[166] add at room temperature. The addition of HCl is more difficult and usually requires heat,[23] although HCl adds easily in the presence of silica gel.[167] The reaction has been carried out with a large variety of double-bond compounds, including

conjugated systems, where both 1,2- and 1,4-addition are possible. A convenient method for the addition of HF involves the use of a polyhydrogen fluoride-pyridine solution.[168] When the substrate is mixed with this solution in a solvent, such as THF at 0°C, alkyl fluorides are obtained in moderate-to-high yields.

The addition of hydrogen halides to simple alkenes, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with Markovnikov's rule.[169] The addition follows second order kinetics.[170] When peroxides are added, the addition of HBr occurs by a free-radical mechanism and the orientation is anti-Markovnikov (p. 1021).[171] It must be emphasized that this is true *only* for HBr. Free-radical addition of HF and HI has never been observed, even in the presence of peroxides, and of HCl only rarely. In the rare cases where free-radical addition of HCl was noted, the orientation was still Markovnikov, presumably because the more stable *product* was formed.[172] Free-radical addition of HF, HI, and HCl is energetically unfavorable (see the discussions on pp. 943, 959). It has often been found that anti-Markovnikov addition of HBr takes place even when peroxides have not been added. This happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (**14-7**). Markovnikov addition can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve, and it is more common to add inhibitors, for example, phenols or quinones, which suppress the free-radical pathway. The presence of free-radical precursors, such as peroxides does not inhibit the ionic mechanism, but the radical reaction, being a chain process, is much more rapid than the electrophilic reaction. In most cases, it is possible to control the mechanism (and hence the orientation) by adding peroxides to achieve complete free-radical addition, or inhibitors to achieve complete electrophilic addition, although there are some cases where the ionic mechanism is fast enough to compete with the free-radical mechanism and complete control cannot be attained. Markovnikov addition of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase-transfer catalysis.[173] For alternative methods of adding HBr (or HI) with anti-Markovnikov orientation, see **12-31**.

It is also possible to add 1[174] or 2 equivalents of any of the four hydrogen halides to triple bonds. Markovnikov's rule ensures that *gem*-dihalides and not *vic*-dihalides

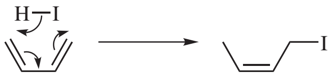
are the products of the addition of two equivalents.

$$—C \quad C— \xrightarrow{HX} —CH{=}CX— \xrightarrow{HX} —CH_2—CX_2—$$

Chlorotrimethylsilane can be added to alkenes to give alkyl chlorides. 1-Hexene reacts with Me_3SiCl in water to give 2-chlorohexane.[175] Treatment of an alkene with KHF_2 and SiF_4 leads to the alkyl fluoride,[176] and bromotrimethylsilane adds to alkynes to give the vinyl bromide.[177] Trichloroisocyanuric acid reacts with terminal alkenes in water to give the 1-chloro alkane.[178]

HX are electrophilic reagents, and many polyhalo and polycyano alkenes, for example, $Cl_2C{=}CHCl$, do not react with them at all in the absence of free-radical conditions. Vinylcyclopropanes, however, react with opening of the cyclopropane ring to give a homoallylic chloride.[179] When such reactions do occur, however, they take place by a nucleophilic addition mechanism, that is, initial attack is by X^-. This type of mechanism also occurs with Michael-type substrates C=C—Z,[180] There the orientation is always such that the halogen goes to the carbon that does not bear the Z, so the product is of the form X—C—CH—Z, even in the presence of free-radical initiators. Hydrogen iodine adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism:[181]



HX can be added to ketenes[182] to give acyl halides:

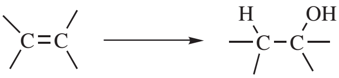
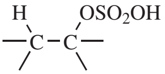
B. Oxygen on the Other Side

15-3 Hydration of Double bonds

Hydro-hydroxy-addition

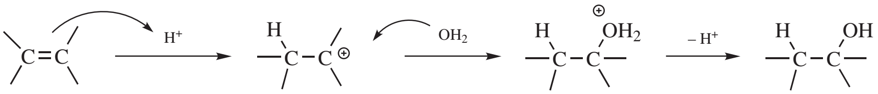


Double bonds can be hydrated by treatment with water and an acid catalyst. The most common catalyst is sulfuric acid, but other acids that have relatively non-nucleophilic counterions, such as nitric or perchloric can also be used. The mechanism is electrophilic and begins with attack of the π-bond on an acidic proton (see p. 1005). The resulting carbocation is then attacked by negative species, such as HSO_4^- (or similar counterion in the case of other acids), to give the initial product **32**, which can be isolated in some cases, but under the conditions of the



32

reaction, is usually hydrolyzed to the alcohol (**10-4**). However, the conjugate base of the acid is not the only possible species that attacks the initial carbocation. The attack can also be by water to form **33**.



33

When the reaction proceeds by this pathway, **32** and similar intermediates are not involved and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of El elimination of alcohols (**17-1**).[183] It is likely that the mechanism involves both pathways. *The initial carbocation occasionally rearranges to a more stable one.* For example, hydration of CH_2=$CHCH(CH_3)_2$ gives $CH_3CH_2COH(CH_3)_2$. With ordinary alkenes the addition predominantly follows Markovnikov's rule. Another method for Markovnikov addition of water consists of simultaneously adding an oxidizing agent (O_2) and a reducing agent (either Et_3SiH[184] or a secondary alcohol, e.g., 2-propanol[185]) to the alkene in the presence of a cobalt-complex catalyst. No rearrangement is observed with this

[183]For discussions of the mechanism, see Vinnik, M.I.; Obraztsov, P.A. *Russ. Chem. Rev.* ***1990***, *59*, 63; Liler, M. *Reaction Mechanisms in Sulphuric Acid*, Academic Press, NY, ***1971***, pp. 210–225.

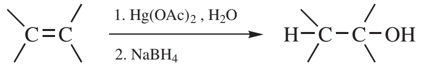
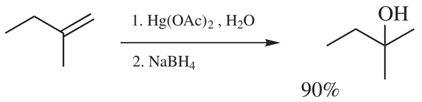
method. The corresponding alkane and ketone are usually side products.



Alkenes can be hydrated quickly under mild conditions in high yields without rearrangement products by the use of *oxymercuration*[186] (addition of oxygen and mercury) followed by *in situ* treatment with sodium borohydride[187] (**12-24**). For example, 2-methyl-1-butene treated with mercuric acetate,[188] followed by $NaBH_4$, gave 2-methyl-2-butanol.



This method, which is applicable to mono-, di-, tri-, and tetraalkyl as well as phenyl-substituted alkenes, gives almost complete Markovnikov addition. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate without, in general, causing difficulties.[189] When two double bonds are present in the same molecule, the use of ultrasound allows oxymercuration of the less-substituted one without affecting the other.[190] A related reaction treats an alkene with zinc borohydride on silica gel to give a 35:65 mixture of secondary:primary alcohols.[191]

Water can be added indirectly, with anti-Markovnikov orientation, by treatment of the alkene with a 1:1 mixture of $PhCH_2NEt_3^+ \ BH_4^-$ and Me_3SiCl, followed by addition of an aqueous solution of K_2CO_3.[192] Reaction of alkenes with $Ti(BH_4)_3$, and then aqueous K_2CO_3 also leads to the anti-Markovnikov alcohol.[193] Reaction of

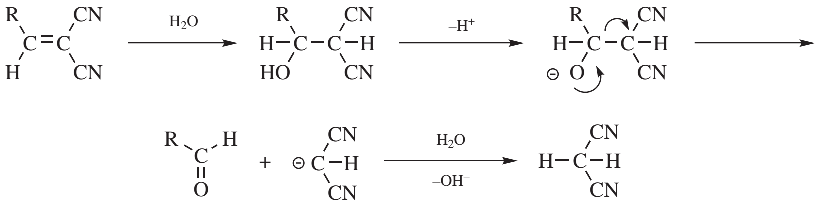
terminal alkynes with water and ruthenium catalyst, followed by sequential treatment with long chain sulfates and then ammonium salts gave the aldehyde via anti-Markovnikov addition of water.[194] With substrates of the type C=C–Z (Z is as defined on p. 1007) the product is almost always HO—C—CH—Z and the mechanism is usually nucleophilic,[195] although electrophilic addition gives the same product[196] since a cation CH—C—Z would be destabilized by the positive charges (full or partial) on two adjacent atoms. However, the α-hydroxy compound HC—CH(OH)Z, was obtained by treatment of the substrate with O_2, $PhSiH_3$, and a manganese- complex catalyst.[197] When the substrate is of the type RCH=CZZ′, CZZ′, addition of water may result in cleavage of the adduct, to give an aldehyde and CH_2ZZ', **34**.[198] The cleavage step is an example of **12-41**



34

For another method of anti-Markovnikov hydration, see hydroboration (**15-16**).

Alkenes react with PhO_2BH and a niobium catalyst, followed by oxidation with $NaOO^-$, to give the alcohol,[199] and Cp_2TiCl_4 can also be used.[200] Reaction with $HSiCl_3$ and a chiral palladium catalyst, followed by reaction with KF and hydrogen peroxide, leads to the alcohol with high asymmetric induction.[201] Conjugated alkenes also react with $PhSiH_2$ and oxygen, with a manganese catalyst, to give an α-hydroxy ketone.[202] Alkenes react with molecular oxygen in the presence of a cobalt porphyrin catalyst, and reduction with $P(OMe)_3$ leads to the secondary alcohol.[203] This procedure has also been used to hydrate conjugated dienes,[204] although conjugated dienes are seldom hydrated.

The addition of water to enol ethers causes hydrolysis to aldehydes or ketones (**10-6**). Ketenes add water to give carboxylic acids ($R_2C{=}C{=}O \rightarrow R_2COOH$) in a reaction catalyzed by acids:[205]

OS **IV**, 555, 560; **VI**, 766. Also see, OS **V**, 818.

15-4 Hydration of Triple Bonds

Dihydro-oxo-biaddition

The hydration of triple bonds is generally carried out with mercuric ion salts (often the sulfate or acetate) as catalysts.[206] Mercuric oxide in the presence of an acid is also a common reagent. Since the addition follows Markovnikov's rule, only acetylene gives an aldehyde. All other triple-bond compounds give ketones (for a method of reversing the orientation for terminal alkynes, see **15-16**). With alkynes of the form RC≡CH methyl ketones are formed almost exclusively, but with RC≡CR′ both possible products are usually obtained. The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resinsulfonic acid, see p. 236).[207] Terminal alkynes react with water at 200°C with microwave irradiation to give the corresponding methyl ketone.[208] A gold catalyst was used in aqueous methanol with 50% sulfuric acid to convert terminal alkynes to the ketone.[209] Conversion of phenyl acetylene to acetophenone was accomplished in water at 100°C with a catalytic amount of Tf_2NH (trifluoromethanesulfonimide).[210] In a modified reaction, internal alkynes were treated with 2-aminophenol in refluxing dioxane using a palladium catalyst to produce the corresponding ketone.[211]

Hydration of terminal alkynes can proceed with anti-Markovnikov addition. When 1-octyne was heated with water, isopropanol and a ruthenium catalyst, for example, the product was octanal.[212] A similar reaction was reported in aqueous acetone using a ruthenium catalyst.[213] The presence of certain functionality can

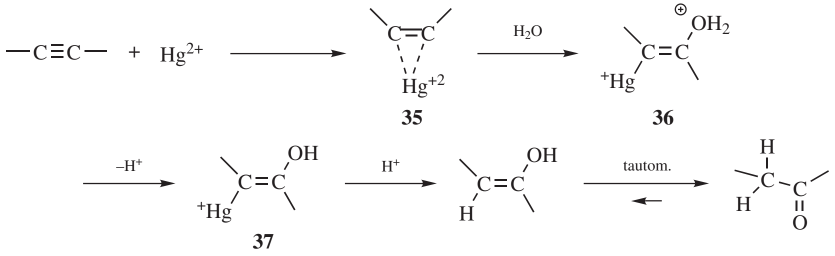
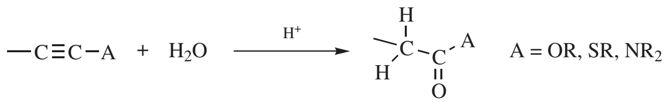
influence the regioselectivity of hydration. 1-Seleno alkynes, such as PhSe-C≡C-Ph, react with tosic acid in dichloromethane to give a seleno ester PhSeC(=O)SH_2Ph after treatment with water.[214]

The first step of the mechanism is formation of a complex (**35**) (ions like Hg^{2+} form complexes with alkynes, p. 115). Water then attacks in an S_N2-type process to give the intermediate **36**,



which loses a proton to give **37**. Hydrolysis of **37** (an example of **12-34**) gives the enol, which tautomerizes to the product. A spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.[215]

Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,[216] and ynamines, without a mercuric catalyst:[217]



This is ordinary electrophilic addition, with rate-determining protonation as the first step.[218] Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.[219] Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.[220] Lactones have been prepared from trimethylsilyl alkenes containing an hydroxyl unit elsewhere in the molecule, when reacted with molecular oxygen, $CuCl_2$, and a palladium catalyst.[221]

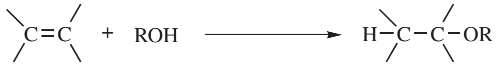
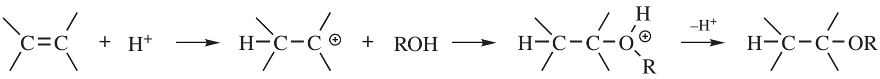
15-5 Addition of Alcohols and Phenols

Hydro-alkoxy-addition



The addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid catalyzed, the mechanism is electrophilic, with H^+ as the species attacked by the π-bond. The resulting carbocation combines with a molecule of alcohol to give an oxonium ion, **38**.



38

The addition, therefore, follows Markovnikov's rule. Primary alcohols give better results than secondary, and tertiary alcohols are very inactive. This is a convenient method for the preparation of tertiary ethers by the use of a suitable alkene, such as $Me_2C{=}CH_2$. Addition of alcohols to allylic systems can proceed with rearrangement, and the use of chiral additive can lead to asymmetric induction.[223]

Alcohols add intramolecularly to alkenes to generate cyclic ethers, often bearing a hydroxyl unit,.[224] but not always.[225] Furan derivatives are available for alkene-ketones using $CuCl_2$ and a palladium catalyst,[226] but chromium catalysts have been used for a similar purpose.[227] A gold catalyst was used with conjugated ketones bearing an alkyne substituent to give fused-ring furans.[228] Pyrone derivatives are available by the coupling of conjugated ketones bearing an alcohol unit, via an addition

elimination process mediated by a palladium catalyst.[229] Intramolecular addition of alcohols to alkenes can be promoted by a palladium catalyst, with migration of the double bond in the final product.[230] Rhenium compounds,[231] titanium compounds,[232] or platinum compounds[233] facilitate this cyclization reaction to form functionalized tetrahydrofurans or tetrahydrofurans. Allylic alcohols have been converted to 2-bromo oxetanes using $Br(collidine)_2^+\ PF_6$.[234] It is noted that the reaction of an alkene–alcohol and *N*-iodosuccinimide with a chiral titanium catalyst leads to a tetrahydrofuran with a pendant iodoalkyl group, with modest enantioselectivity.[235]

Allenes react with alcohols and allenic alcohols have been converted to tetrahydrofuran derivatives bearing a vinyl group at the α-position, using diphenyliodonium salts.[236] In the presence of allylic bromide and a palladium catalyst, allenic alcohols lead to allylically substituted dihydrofurans.[237] Intramolecular addition of alcohols to allenes leads to cyclic vinyl ethers.[238] Alcohols add intramolecularly to a vinylidene dithiane under electrolytic conditions to form a tetrahydrofuran derivative with a pendant dithiane group.[239]

In the presence of other reagents, functionalized ethers can be formed. In methanol with an R—Se—Br reagent, alkenes are converted to selenoalkyl ethers (MeO—C—C—SeR).[240]

An interesting "double" addition was reported in which 2-(hydroxymethyl)phenol reacted with 2,3-dimethyl-2-butene in the presence of lithium perchlorate and Montmorillonite clay/water to give benzopyrans, but the reaction proceeded via an *O*-quinomethane generated *in situ*.[241]

Alcohols add to alkynes under certain conditions to give vinyl ethers. In an excess of alcohol, and in the presence of a platinum catalyst, internal alkynes are converted to ketals.[242] The alcohol to alkyne addition reaction is quite useful for the preparation of heterocycles. Dihydrofurans,[243] furans,[244] benzofurans,[245] and pyran

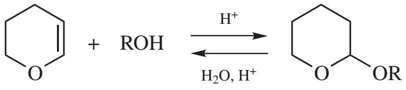
derivatives[246] have been prepared using this approach. Tetrahydrofurans bearing an exocyclic double bond (vinylidene tetrahydrofurans) were prepared from alkynyl alcohols and a silver carbonate catalyst.[247]

For those substrates, more susceptible to nucleophilic attack, for example, polyhalo alkenes and alkenes of the type C=C—Z, it is better to carry out the reaction in basic solution, where the attacking species is RO^-.[248] The reactions with C=C—Z are of the Michael type, and OR goes to the side away from the Z.[249] Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction.[250] Because enol ethers are more susceptible than triple bonds to electrophilic attack, the addition of alcohols to enol ethers can also be catalyzed by acids.[251] One utilization of this reaction involves the compound dihydropyran



39 **40**

(**39**), which is often used to protect the OH groups of primary and secondary[252] alcohols and phenols.[253] The tetrahydropyranyl acetal formed by this reaction (**40**) is stable to bases, Grignard reagents, $LiAlH_4$, and oxidizing agents, any of which can be used to react with functional groups located within the R group. When the reactions are completed, **40** is easily cleaved by treatment with dilute acids (**10-6**). The addition of alcohols to enol ethers is also catalyzed by $CoCl_2$.[254]

Conjugate addition of alcohols to conjugated esters, using ceric ammonium nitrate and LiBr, gave the corresponding α-bromo-β-alkoxy ester.[255]

In base-catalyzed addition to triple bonds, the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions. Other catalysts, namely, BF_3 and mercuric salts, have also been used in addition of ROH to triple bonds.

Alcohols can be added to certain double-bond compounds (cyclohexenes, cycloheptenes) photochemically[256] in the presence of a photosensitizer such as benzene. The mechanism is electrophilic and Markovnikov orientation is found. The alkenes react in their first excited triplet states.[257]

The oxymercuration–demercuration procedure mentioned in **15-3** can be adapted to the preparation of ethers (Markovnikov orientation) if the oxymercuration is carried out in an alcohol ROH as solvent,[258] for example 2-methyl-1-butene in ethanol gives $EtMe_2COEt$.[259] Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols it is necessary to use mercuric trifluoroacetate.[260] However, even this reagent fails where the product would be a ditertiary ether. It is possible to combine the alcohol reactant with another reagent. The reaction of an alkene with iodine and allyl alcohol, in the presence of HgO, gave the *vic*-iodo ether.[261] Alkene-alcohols react with mercuric trifluoroacetate and the aq. KBr (with $LiBH_4/BEt_3$) to give a derivative bearing an iodoalkyl substituent, —O—C—CH(I)R.[262] Alkynes generally give acetals. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with $NaBH_4$) is an alkyl peroxide (peroxy-mercuration).[263] This can be done intramolecularly.[264]

Both alcohols and phenols add to ketenes to give carboxylic esters $[R_2C{=}C{=}O + ROH \rightarrow R_2CHCO_2R]$.[265] This has been done intramolecularly (with the ketene end of the molecule generated and used *in situ*) to form medium- and large-ring lactones.[266] In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates. 1,4-Asymmetric induction is possible when chiral alcohols add to ketenes.[267]

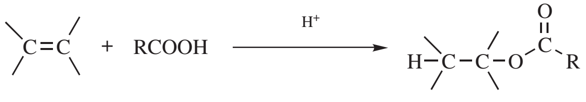
15-6 Addition of Carboxylic Acids to Form Esters

Hydro-acyloxy-addition



Carboxylic esters are produced by the addition of carboxylic acids to alkenes, a reaction that is usually acid-catalyzed (by proton or Lewis acids[268]) and similar in mechanism to **15-5**. Since Markovnikov's rule is followed, hard-to-get esters of tertiary alcohols can be prepared from alkenes of the form $R_2C{=}CHR$.[269] A combination of V_2O_5 and trifluoroacetic acid converts alkenes to trifluoroacetate esters.[270] When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the addition occurs internally and the product is a γ- and/or a δ-lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double-bond shifts (**12-2**).[271] The double bond always migrates (also see, **15-1**) to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. The use of a chiral *Cinchonidine* alkaloid additive leads to lactone formation with modest enantioselectivity.[272] In the presence of diphenyl diselenide and DDQ, alkene carboxylic acids react of form the lactone with a phenylselenomethyl group ($PhSeCH_2$—) at C-5.[273] Carboxylic esters have also been prepared by the acyloxymercuration-demercuration of alkenes (similar to the procedures mentioned in **15-3** and **15-4**).[274] Conjugated esters has been converted to β-lactones with photolysis and added tributyltin hydride, radical cyclization conditions (**15-30**).[275] Addition of carboxylic acids to alkenes to form esters or lactones is catalyzed by palladium compounds.[276] Thallium acetate also promotes this cyclization reaction.[277]

Triple bonds can give enol esters[278] or acylals when treated with carboxylic acids. Mercuric salts are usually catalysts,[279] and vinylic mercury compounds  are intermediates.[280] Terminal alkynes RC≡CH react with CO_2, a secondary amine R'_2 NH, and a ruthenium complex catalyst, to give enol carbamates RCH=CHOC(=O)NR. [281] This reaction has also been performed intramolecularly, to produce unsaturated lactones.[282] Cyclic unsaturated lactones (internal vinyl esters) have been generated from alkyne-carboxylic acids using a palladium catalyst[283] or a ruthenium catalyst.[284] Carboxylic esters can also be obtained by the addition to alkenes of diacyl peroxides.[285] These reactions are catalyzed by copper and are free-radical processes.

Allene carboxylic acids have been cyclized to butenolides with copper(II) chloride.[286] Allene esters were converted to butenolides by treatment with acetic acid and LiBr.[287] Cyclic carbonates can be prepared from allene alcohols using carbon dioxide and a palladium catalyst, and the reaction was accompanied by arylation when iodobenzene was added.[288] Diene carboxylic acids have been cyclized using acetic acid and a palladium catalyst to form lactones that have an allylic acetate elsewhere in the molecule.[289] With ketenes, carboxylic acids give anhydrides[290] and acetic anhydride is prepared industrially in this manner [$CH_2{=}C{=}O + MeCO_2H \rightarrow (MeC{=}O)_2O$].

Sulfonic acids add to alkenes and alkynes. The reaction of an alkyne with *para*-toluenesulfonic acid and treatment with silica gives the vinyl sulfonate (C=C–OSO_2Tol).[291] Cyclic sulfonates can be generated by the reaction of an allylic sulfonate salt (C=C–C–OSO_3^-) with silver nitrate in acetonitrile containing an excess of bromine and a catalytic amount of water.[292] Sultones are formed when alkenes react with PhIO and two equivalents of Me_2SiSO_3Cl.[293]

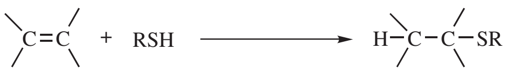
C. Sulfur on the Other Side

15-7 Addition of H_2S and Thiols

Hydro-alkylthio-addition



Hydrogen sulfide (H_2S) and thiols add to alkenes to give alkyl thiols or sulfides by electrophilic, nucleophilic, or free-radical mechanisms.[294] In the absence of initiators, the addition to simple alkenes is by an electrophilic mechanism, similar to that in **15-5**, and Markovnikov's rule is followed. However, this reaction is usually very slow and often cannot be done or requires very severe conditions unless a proton or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated H_2SO_4[295] or together with $AlCl_3$.[296] In the presence of free-radical initiators, H_2S and thiols add to double and triple bonds by a free-radical mechanism and the orientation is anti-Markovnikov.[297] The addition of thiophenol to an alkene with a zeolite also leads to the anti-Markovnikov sulfide.[298] Additives can influence the regioselectivity. Styrene reacts with thiophenol to give primarily the anti-Markovnikov product, whereas addition of thiophenol in the presence of Montmorillonite K10 clay gives primarily the Markovnikov addition product.[299] In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free-radical addition can be done with H_2S, RSH (R may be primary,

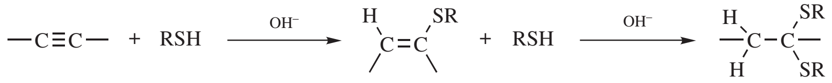
secondary, or tertiary), ArSH, or RCOSH.[300] The R group may contain various functional groups. The alkenes may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, COOH, COOR, NO_2, RSO_2, and so on. Addition of Ph_3SiSH to terminal alkenes under radical conditions also leads to the primary thiol.[301]

Alkynes react with thiols to give vinyl sulfides. With alkynes it is possible to add 1 or 2 equivalents of RSH, giving a vinyl sulfide[302] or a dithioketal, respectively. Alternative preparations are available, as in the reaction of a terminal alkyne with $Cp_2Zr(H)Cl$ followed by PhSCl to give the vinyl sulfide with the SPh unit at the less substituted position (PhCH=CHSPh).[303] The intramolecular addition of a thiol to an ene-yne, with a palladium catalyst, leads to substituted thiophene derivatives.[304]

The fundamental addition reaction can be modified by the use of transition metals and different reagents. Alkenes react with diphenyl disulfide in the presence of $GaCl_3$ to give the product with two phenylthio units, PhS–C–C–SPh).[305] The reaction of an alkyne with diphenyl disulfide and a palladium catalyst leads to the bis-vinyl sulfide, PhS–C=C–SPh.[306]

When thiols are added to substrates susceptible to nucleophilic attack, bases catalyze the reaction and the mechanism is nucleophilic. These substrates may be of the Michael type[307] or may be polyhalo alkenes or alkynes.[250] As with the free-radical mechanism, alkynes can give either vinylic thioethers or dithioacetals:



Thiols add to alkenes under photochemical conditions to form thioethers, and the reaction can be done intramolecularly to give cyclic thioethers.[308] Thiols also add to alkynes and with a palladium catalyst, vinyl sulfides can be formed.[309] Thiocarbonates function as thiol surrogates, converting alkenes to alkyl thiol in the presence of $TiCl_4$; and CuO.[310]

By any mechanism, the initial product of addition of H_2S to a double bond is a thiol, which is capable of adding to a second molecule of alkene, so that sulfides

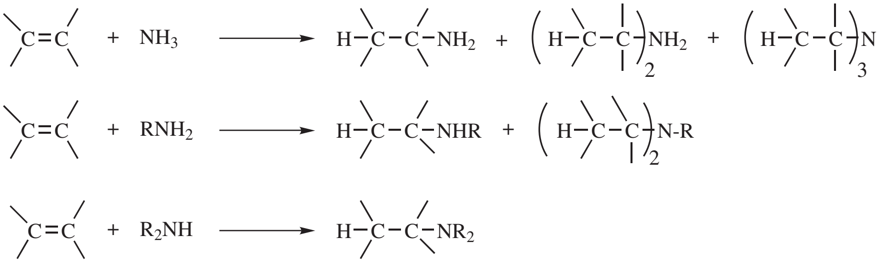
D. Nitrogen or Phosphorus on the Other Side

15-8 Addition of Ammonia and Amines, Phosphines, and Related Compounds

Hydro-amino-addition
Hydro-phosphino-addition



Ammonia and primary and secondary amines add to alkenes *that are susceptible* to nucleophilic attack.[314] Ammonia and amines are much weaker acids than water, alcohols, and thiols (see **15-3**, **15-5**, **15-7**) and since acids turn NH_3 into the weak

[311]For an example, see Blake, A.J.; Friend, C.L.; Outram, R.J.; Simpkins, N.S.; Whitehead, A.J. *Tetrahedron Lett.* ***2001***, *42*, 2877.

acid, the ammonium ion NH_4^+, this reaction does not occur by an electrophilic mechanism. The reaction tends to give very low yields, if any, with ordinary alkenes, unless extreme conditions are used (e.g., 178–200°C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH_3 and ethylene[315]). Amine alkenes give cyclic amines as the major product, in good yield, when treated with *n*-butyllithium.[316] Ammonia gives three possible products, since the initial product is a primary amine, which may add to a second molecule of alkene, and so on. Similarly, primary amines give both secondary and tertiary products. In practice it is usually possible to control which product predominates. The mechanism is nearly always nucleophilic, and the reaction is generally performed on polyhalo alkenes[317] and alkynes.[318] Ammonia adds to alkenes photochemically.[319] Reaction of a secondary amine with butyllithium generates an amide base, which reacts with alkenes to give alkyl amines,[320] and can add intramolecularly to an alkene to form a pyrrolidine.[321] Pyrroles can be generated in this manner.[322] *N*-Chloroamines add to alkenes intramolecularly to give β-chloropyrrolidines.[323]

Conjugated carbonyl compounds react via conjugate addition with amines to give β-amino derivatives (see **15-31**)[324] As expected, on Michael-type substrates the nitrogen goes to the carbon that does not carry the Z. With substrates of the form RCH=CZZ′, the same type of cleavage of the adduct can take place as in **15-3**.[325]

There are many examples of transition catalyzed addition of nitrogen compounds to alkenes, alkynes,[326] and so on. Secondary amines can be added to certain nonactivated alkenes if palladium(II) complexes are used as catalysts.[327]

The complexation lowers the electron density of the double bond, facilitating nucleophilic attack.[328] Markovnikov orientation is observed and the addition is anti.[329] Molybdenum,[330] titanium,[331] Yttrium,[332] and rhodium compounds[333] have been used in the addition of amines to alkenes. An intramolecular addition of an amine unit to an alkene to form a pyrrolidine was reported using a palladium catalyst,[334] a lanthanide reagent,[335] or an yttrium reagent.[336] Aniline reacts with dienes and a palladium catalyst to give allylic amines.[337] Diene amines react with samarium catalysts to give 2-alkenyl pyrrolidines.[338] Addition of secondary amines to dihydropyrans using a palladium catalyst gave the corresponding aminal (an α-amino ether).[339] Reduction of nitro compounds in the presence of rhodium catalysts, in the presence of alkenes, CO and H_2, leads to an amine unit adding to the alkene moiety.[340] Secondary amines react with alkenes to give the alkyl amine using a rhodium catalyst in a CO/H_2 atmosphere,[341] but modification of the chromium catalyst and conditions led to an enamine.[342] Note that the reaction of an alkene and a secondary amine with a rhodium catalyst can also give an enamine.[343]

Other nitrogen compounds, among them hydroxylamine and hydroxylamines,[344] hydrazines, and amides (**15-9**), also add to alkenes. Azodicarboxylates (Boc-N=N-Boc) react with alkenes, in the presence of $PhSiH_3$ and a cobalt catalyst, to give

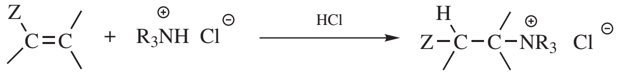
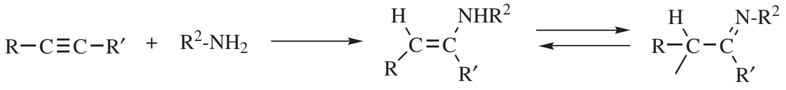
alkylhydrazides [RN(Boc)–NHBoc].[345] Even with amines, basic catalysts are sometimes used, so that RNH^- or R_2N^- is the actual nucleophile. Tertiary amines (except those that are too bulky) add to Michael-type substrates in a reaction that is catalyzed by acids like HCl or HNO_3 to give the corresponding quaternary ammonium salts.[346]



The tertiary amine can be aliphatic, cycloalkyl, or heterocyclic (including pyridine). The reaction of NaOH with an amine containing two distal alkene units, followed by addition of a neodymium catalyst leads to a bicyclic amine.[347]

Primary amines add to triple bonds[348] to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize to the more stable imines, **41**.[349]



41

The reaction has been done with a palladium catalyst,[350] a titanium catalyst,[351] a tantalum catalyst,[352] and with a gold catalyst.[353] An intramolecular addition of amines to an alkyne unit in the presence of a palladium catalyst generated heterocyclic or cyclic amine compounds.[354] The titanium catalyzed addition of primary

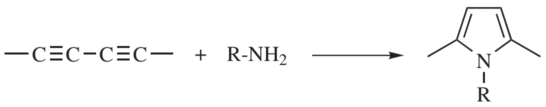
amines to alkynes give the enamine, which can be hydrogenated (**15-11**) to give the corresponding amine.[355] A variation treats an alkynyl imine with CuI to form pyrroles.[356] *N,N*-Diphenylhydrazine reacts with diphenyl acetylene and a titanium catalyst to give indole derivatives.[357] Treatment of an imine of 2-alkynyl benzaldehyde with iodide gave a functionalized isoquinoline.[358] When ammonia is used instead of a primary amine, the corresponding $RH_2C{-}C({=}NH){-}R'$ is not stable enough for isolation, but polymerizes. Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles, **42**.[359] A similar preparation of pyrroles was reported by heating non-conjugated diynes with aniline and a titanium catalyst.[360] This is not 1,4-addition, but 1,2-addition twice. Conjugated ene-ynes containing an amino group also give pyrroles with a palladium catalyst.[361]

Allenes are reaction partners,[362] and amines add to allenes in the presence of a catalytic amount of CuBr[363] or palladium compounds.[364] Intramolecular reaction of allene amines lead to dihydropyrroles, using a gold catalyst.[365]



42

Treatment of an allene amine with a ruthenium catalyst, 10% of $TiCl_4$ and methyl vinyl ketone to give a product of amine addition followed by Michael addition, a pyrrolidine derivative with a pendant alkenyl ketone unit.[366] Cyclic imines can be prepared from allene amines using a titanium catalyst.[367]

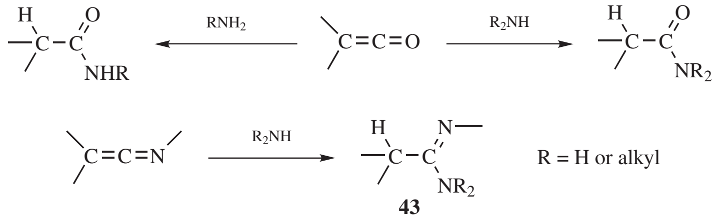
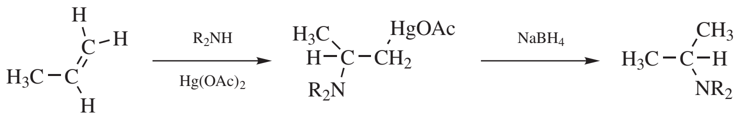
Primary and secondary amines add to ketenes to give, respectively, *N*-substituted and *N,N*-disubstituted amides:[368] and to ketenimines to give amidines, **43**.[369]



43

NH_3 can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (**15-16**) followed by treatment with NH_2Cl or NH_2OSO_2OH (**12-32**). This produces a primary amine with anti-Markovnikov orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration followed by reduction (see **15-3** for the analogous oxymercuration–demercuration procedure), to give amine **45**.[370]



44 **45**

The addition of a secondary amine (shown above) produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows Markovnikov's rule. For conversion of **44** to other products, see **15-53**.

Phosphines add to alkenes to give alkyl phosphines and to alkynes to give vinyl phosphines. In the presence of an ytterbium (Yb) catalyst, diphenylphosphine added to diphenyl acetylene to give the corresponding vinyl phosphine.[371] A palladium catalyst was used for the addition *o*-diphenylphosphine to terminal alkynes, giving the anti-Markovnikov vinyl phosphine but a nickel catalyst led to the Markovnikov vinyl phosphine.[372] Alkenes also react with diarylphosphines

[368]For discussions of the mechanism of this reaction, see Briody, J.M.; Satchell, D.P.N. *Tetrahedron* ***1966***, *22*, 2649; Tidwell, T.T. *Acc. Chem. and a nickel catalyst. to give the alkyl phosphine[373] Silylphosphines ($R_3Si{-}PAr_2$) react with alkenes and Bu_4NF to give the anti-Markovnikov ally phosphine.[374] Phosphine oxides can be prepared by the reaction of an aryl substituted alkene and diphenylphosphine oxide, $Ph_2P(=O)H$.[375] Diphenylphosphine oxide also reacted with terminal alkynes to give the anti-Markovnikov vinyl phosphine oxide using a rhodium catalyst.[376] Phosphonate esters were similar prepared from alkenes and diethyl phosphite, $(EtO_2)P(=O)H$, and a manganese catalyst in a reaction exposed to oxygen.[377] Similar addition was observed in the reaction of an alkene with NaH_2PO_2 to give the phosphinate, $RCH{=}CH_2 \rightarrow RCH_2CH_2PH(=O)ONa$.[378] Palladium catalysts were used for the preparation of similar compounds from alkenes[379] and the reaction of terminal alkynes with dimethyl phosphite and a nickel catalyst gave the Markovnikov vinyl phosphonate ester.[380] Other phosphites were added to dienes to give an allylic phosphonate ester using a palladium catalyst.[381] Diarylphosphines react with vinyl ethers and a nickel catalyst to give α-alkoxy phosphonate esters.[382]

15-9 Addition of Amides

Hydro-amido-addition

Under certain conditions, amides can add directly to alkenes to form *N*-alkylated amides. Sulfonamides react in a similar manner. 3-Pentenamide was cyclized to 5-methyl-2-pyrrolidinone by treatment with trifluorosulfonic acid.[383] Acyl hydrazine derivatives also cyclized in the presence of hypervalent iodine reagents to give lactams.[384] When a carbamate was treated with Bu_3SnH, and AIBN, addition to an alkene led to a bicyclic lactam.[385]

[385]Callier, A.-C.; Quiclet-Sire, B.; Zard, S.Z. *Tetrahedron Lett.* ***1994***, *35*, 6109.

The reaction can be done intramolecularly. *N*-Benzyl pent-4-ynamide reacted with tetrabutylammonium fluoride to an alkylidene lactam.[386] Similar addition of a tosylamide-alkene, with a palladium catalyst, led to a vinyl *N*-tosyl pyrrolidine.[387] Similar cyclization reactions occur with tosylamide-alkynes.[388]

Treatment of triflamide alkenes with triflic acid gives the corresponding *N*-triflyl cyclic amine.[389] Using an alkene halide and an *N*-chlorosulfonamide, an amide is generated *in situ*, and addition to the alkene gives a pyrrolidine derivative.[390] *N*-Bromocarbamates also add to alkenes, in the presence of $BF_3•OEt_2$ to give a *vic*-bromo *N*-Boc amine.[391] The titanium catalyzed reaction of alkenyl *N*-tosylamines give *N*-tosyl cyclic amines.[392]

Alkynes and allenes also react with amides. Phenylthiomethyl alkynes were converted to *N*-Boc-*N*-phenylthio allenes with Boc azide and an iron catalyst.[393] The palladium-catalyzed reaction of an allene amide, with iodobenzene, leads to *N*-sulfonyl aziridines having an allylic group at C1.[394] Other allene *N*-tosylamines similarly give *N*-tosyl tetrahydropyridines.[395]

Imides can also add to alkenes or alkynes. Ethyl 2-propynoate reacted with phthalimide, in the presence of a palladium catalyst, to give ethyl 2-phthalimido-2-propenoate.[396]

15-10 Addition of Hydrazoic Acid

Hydro-azido-addition

Hydrazoic acid (HN_3) can be added to certain Michael-type substrates (Z is as defined on p. 1007) to give β-azido compounds.[397] The reaction apparently fails if R

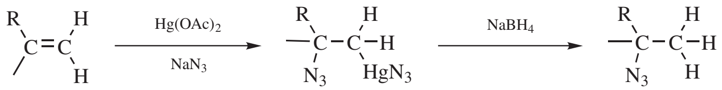
is phenyl. The HN_3 also adds to enol ethers $CH_2{=}CHOR$ to give $CH_3{-}CH(OR)N_3$, and to silyl enol ethers,[398] but it does not add to ordinary alkenes unless a Lewis acid catalyst, such as $TiCl_4$, is used, in which case good yields of azide can be obtained.[398] Hydrazoic acid can also be added indirectly to ordinary alkenes by azidomercuration, followed by demercuration,[399] analogous to the similar procedures

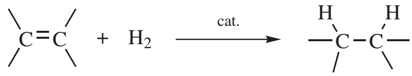


mentioned in **15-3**, **15-5**, **15-6**, and **15-8**. The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene) but fails for unstrained internal alkenes.

E. Hydrogen on Both Sides

15-11 Hydrogenation of Double and Triple Bonds[400]

Dihydro-addition



Most carbon–carbon double bonds, whether substituted by electron-donating or electron-withdrawing substituents, can be catalytically hydrogenated, usually in quantitative or near-quantitative yields.[401] Almost all known alkenes added hydrogen at temperatures between 0 and 275°C. The catalysts used can be divided into

two broad classes, both of which mainly consist of transition metals and their compounds: (*1*) catalysts insoluble in the reaction medium (*heterogeneous catalysts*). Among the most effective are Raney nickel,[402] palladium-on-charcoal (perhaps the most common),[403] $NaBH_4$-reduced nickel[404] (also called nickel boride), platinum metal or its oxide, rhodium, ruthenium, and zinc oxide.[405] (*2*) Catalysts soluble in the reaction medium (*homogeneous catalysts*).[406] An important example is chlorotris(triphenylphosphine)rhodium, $RhCl(Ph_3P)_3$,[407] (**100**, *Wilkinson's catalyst*),[408] which catalyzes the hydrogenation of many alkenyl compounds without disturbing such groups as COOR, NO_2, CN, or COR present in the same molecule.[409] Even unsaturated aldehydes can be reduced to saturated aldehydes,[410] although in this case decarbonylation (**14-32**) may be a side reaction. In general, for catalytic hydrogenation, many functional groups may be present in the molecule, for example, OH, COOH, NR_2 including NH_2, N(R)COR′ including carbamates,[411] CHO, COR, COOR, or CN. Vinyl esters can be hydrogenated using homogeneous rhodium catalyst.[412] Enamides are hydrogenated, with excellent enantioselectivity, using chiral rhodium catalysts.[413] Some of these groups are also susceptible to catalytic reduction, but it is usually possible to find conditions

[402]For a review of Raney nickel, see Pizey, J.S. *Synthetic Reagents*, Vol. 2, Wiley, NY, ***1974***, pp. 175–311. Double bonds have been reduced with Raney nickel alone; with no added H_2. under which double bonds can be reduced selectively[414] (see Table 19.2). Controlling the solvent allows catalytic hydrogenation of an alkene in the presence of an aromatic nitro group.[415]

Among other homogeneous catalysts are chlorotris(triphenylphosphine)hydridoruthenium(II), $(Ph_3P)_3RuClH$,[416] which is specific for terminal double bonds (other double bonds are hydrogenated slowly or not at all), and pentacyanocobaltate(II), $Co(CN)_5^{3-}$, which is effective for double and triple bonds only when they are part of conjugated systems[417] (the conjugation may be with C=C, C=O, or an aromatic ring). Colloidal palladium has also been used as a catalyst,[418] and a polymer bound ruthenium catalyst has also been used.[419] A polymer incarcerated palladium catalyst gave the hydrogenated product in quantitative yields.[420] Rhodium on mesoporous silica can be used to hydrogenate alkenes.[421] A nanoparticulate palladium catalyst in an ionic liquid has been used for the hydrogenation of alkenes.[422]

Homogeneous catalysts often have the advantages of better catalyst reproducibility and better selectivity. They are also less susceptible to catalyst poisoning[423] (heterogeneous catalysts are usually poisoned by small amounts of sulfur, often found in rubber stoppers, or by sulfur-containing compounds, such as thiols and sulfides).[424] On the other hand, heterogeneous catalysts are usually easier to separate from the reaction mixture.

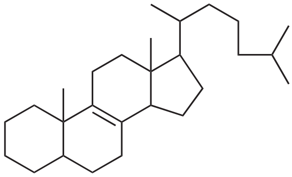
Unfunctionalized alkenes are hydrogenated with good diastereoselectivity and enantioselectivity using various metal catalysts and chiral ligands.[425] Soluble, chiral homogeneous catalysts are usually the best choice, especially for alkenes. The transition-metal catalyst (rhodium and ruthenium are probably the most common) is usually prepared with suitable chiral ligands prior to addition to the reaction, or an achiral catalyst, such as Wilkinson's catalyst, **100**: $RhCl(Ph_3P)_3$, is added along with a chiral ligand. The chiral ligand is typically a phosphine. In one case, the phosphorous may be chiral, as in **101** (called R-camp),[426] but pyramidal inversion at elevated temperatures (see p. 142) limits the utility of such ligands. The alliterative is to prepare a phosphine containing a chiral carbon, and bis(phosphines), such as **102** (called dipamp)[427] are the most common. There are many variations of chiral bis(phosphine) ligands. Mono-phosphine ligands have also been used.[428] Titanocenes[429] with chiral cyclopentadienyl ligands have given enantioselective hydrogenation of unfunctionalized alkenes, such as 2-phenyl-1-butene.[430] Chiral poisoning has been used as a strategy for asymmetric catalysis.[431]

Hydrogenations in most cases are carried out at room temperature and just above atmospheric pressure, but some double bonds are more resistant and require higher temperatures and pressures. The resistance is usually a function of increasing substitution and is presumably caused by steric factors. Trisubstituted double bonds require, say, 25°C and 100 atm, while tetrasubstituted double bonds may require 275°C and 1000 atm. Among



103

the double bonds most difficult to hydrogenate or which cannot be hydrogenated at all are those common to two rings, as in steroid **103**. Hydrogenations, even at about atmospheric pressure, are ordinarily performed in a special hydrogenator, but this is

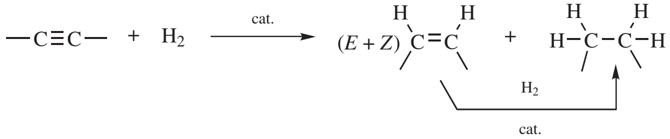
not always necessary. Both the catalyst and the hydrogen can be generated *in situ*, by treatment of H_2PtCl_6 or $RhCl_3$ with $NaBH_4$;[432] ordinary glassware can then be used. The great variety of catalysts available often allows an investigator to find one that is highly selective. For example, the catalyst Pd(salen) encapsulated in zeolites permitted the catalytic hydrogenation of 1-hexene in the presence of cyclohexene.[433] It has been shown that the pressure of the reaction can influence enantioselectivity in asymmetric catalytic hydrogenations.[434]



Triple bonds can be reduced, either by catalytic hydrogenation or by the other methods mentioned in the following two sections. The comparative reactivity of triple and double bonds depends on the catalyst. With most catalysts (e.g., Pd), triple bonds are hydrogenated more easily, and therefore it is possible to add just 1 equivalent of hydrogen and reduce a triple bond to a double bond (usually a stereoselective syn addition) or to reduce a triple bond without affecting a double bond present in the same molecule.[435] A particularly good catalyst for this purpose is the Lindlar catalyst (Pd-$CaCO_3$—PbO).[436] An alternative catalyst used for selective hydrogenation to cis-alkenes is palladium on barium sulfate ($BaSO_4$) catalyst, poisoned with quinoline[437] (sometimes called the *Rosenmund catalyst*). Palladium on calcium carbonate in polyethylene glycol (PEG) has also bee used as a recyclable catalyst system.[438] Hydrogenation using a palladium catalyst on pumice was shown to give the cis-alkene with excellent selectivity.[439] Hydrogenation of a C≡C unit occurs in the presence of other functional groups, including NR_2 including NH_2,[440] and sulfonyl.[441]

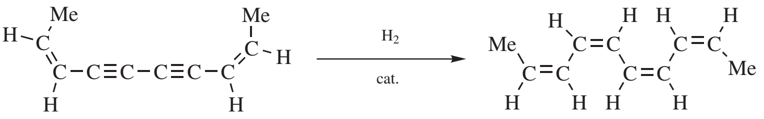
Conjugated dienes can add hydrogen by 1,2- or 1,4-addition. Selective 1,4-addition can be achieved by hydrogenation in the presence of carbon monoxide, with bis(cyclopentadienyl)chromium as catalyst.[442] With allenes[443] catalytic hydrogenation usually reduces both double bonds.

Most catalytic reductions of double or triple bonds, whether heterogeneous or homogeneous, have been shown to be syn, with the hydrogens entering from the less-hindered side of the molecule.[444] Stereospecificity can be investigated only for tetrasubstituted alkenes (except when the reagent is D_2), which are the hardest to hydrogenate, but the results of these investigations show that the addition is usually 80–100% syn, although some of the anti addition product is normally also found and in some cases predominates. Catalytic hydrogenation of alkynes is nearly always stereoselective, giving the cis alkene (usually at least 80%), even when it is thermodynamically less stable. For example, **104** gave **105**, even although the steric hindrance is such that a planar molecule is impossible.[445] This is thus a useful method for preparing cis alkenes.[446] However, when



104 **105**

steric hindrance is too great, the trans alkene may be formed. One factor that complicates the study of the stereochemistry of heterogeneous catalytic hydrogenation is that exchange of hydrogens takes place, as can be shown by hydrogenation with deuterium.[447] Thus deuterogenation of ethylene produced all the possible deuterated ethylenes and ethanes (even C_2H_6), as well as HD.[448] With 2-butene, it was found that double-bond migration, cis–trans isomerization, and even exchange of hydrogen with groups not on the double bond could occur; for example, $C_4H_2D_8$ and C_4HD_9 were detected on treatment of *cis*-2-butene with deuterium and a catalyst.[449] Indeed, *alkanes* have been found to exchange with deuterium over a catalyst,[450] and even without deuterium, for example, $CH_4 + CD_4 \rightarrow CHD_3 + CH_3D$

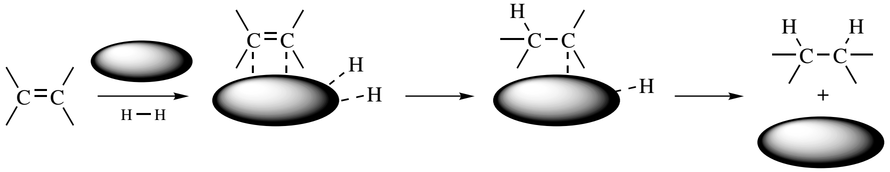
D in the gas phase, with a catalyst. All this makes it difficult to investigate the stereochemistry of heterogeneous catalytic hydrogenation.



The mechanism of the heterogeneous catalytic hydrogenation of double bonds is not thoroughly understood because it is a very difficult reaction to study.[451] Because the reaction is heterogeneous, kinetic data, although easy to obtain (measurement of decreasing hydrogen pressure), are difficult to interpret. Furthermore, there are the difficulties caused by the aforementioned hydrogen exchange. The currently accepted mechanism for the common two-phase reaction was originally proposed in 1934.[452] According to this, the alkene is adsorbed onto the surface of the metal, although the nature of the actual bonding is unknown,[453] despite many attempts to elucidate it.[454] In the 1934 work, the metallic site was indicated by an asterisk, but here we use . For steric reasons it is apparent that adsorption of the alkene takes place with its less-hindered side attached to the catalyst surface, probably as an η^2 complex (see p. 116). The fact that addition of hydrogen is generally also from the less-hindered side indicates that the hydrogen too is probably adsorbed on the catalyst surface before it reacts with the alkene. It is likely that as the H_2 molecule is adsorbed on (coordinated to) the metal catalyst, cleavage occurs to give η^1- coordinated hydrogen atoms (see p. $$$). Note that this model suggest a single metal particle for coordination of the alkene and the hydrogen atoms, but the hydrogen atoms and the alkene could be coordinated to different metal particles. It has been shown that platinum catalyzes homolytic cleavage of hydrogen molecules.[455] In the second step, one of the adsorbed (η^1-coordinated) hydrogen atoms becomes attached to a carbon atom, creating in effect, an alkyl radical (which is still bound to the catalyst although only by one bond, probably η^1-coordination). Transfer of a hydrogen atom to carbon opens a site on the metal catalyst for coordination to additional hydrogen atoms. Finally, another hydrogen atom (not necessarily the one originally connected to the first hydrogen) combines with the radical

to give the reaction product, freed from the catalyst surface, and the metal catalyst that is now available for coordination of additional hydrogen atoms and/or alkenes. All the various side reactions, including hydrogen exchange and isomerism, can be explained by this type of process.[456] Although this mechanism is satisfactory as far as it goes,[457] there are still questions it does not answer, among them questions[458] involving the nature of the asterisk, the nature of the bonding, and the differences caused by the differing nature of each catalyst.[459]

Heterogeneous catalysis occurs at the surface of the metal catalyst, and there are different types of metal particles on the surface. Maier suggested the presence of **terrace-**, **step-**, and **kink**-type atoms (in Fig. 6.1)[460] on the surface of a heterogeneous catalyst. These terms refer to different atom types, characterized by the number of nearest neighbors,[460] which correspond to different transition-metal fragments, as well as to different coordination states of that metal.[461] A terrace-type atom (A in Fig. 15.1) typically has eight or nine neighbors and corresponds to a geometry shown for the ML_5 particle. The step type of atom (B) usually has seven neighbors and can be correlated with the geometry shown for the ML_4

[456]Smith, G.V.; Burwell Jr., R.L. *J. Am. Chem. Soc.* ***1962***, *84*, 925.

[457]A different mechanism has been proposed by Zaera, F.; Somorjai, G.A. *J. Am. Chem. Soc.* ***1984***, *106*, 2288, but there is evidence against it: Beebe, Jr., T.P.; Yates Jr., J.T. *J. Am. Chem. Soc.* ***1986***, *108*, 663. See also, Thomson, S.J.; Webb, G. *J. Chem. Soc., Chem. Commun.* ***1976***, 526.

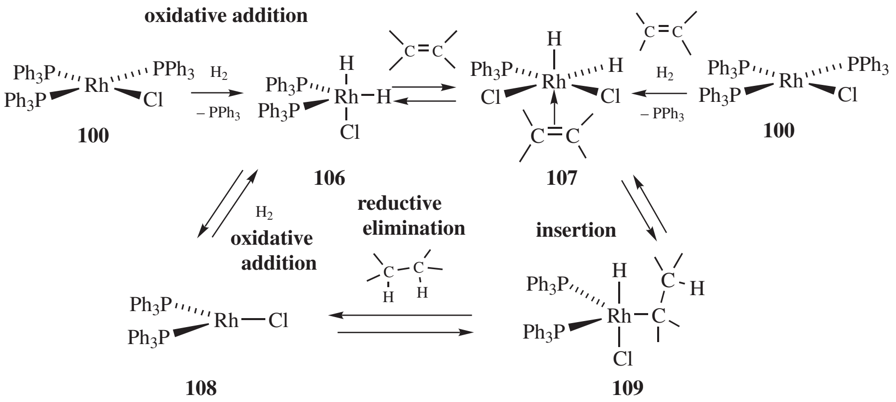
particle. Finally, the kink-type atom (C) has six neighbors and corresponds to geometry shown for the ML_3 particle. In general, as the particle size increases, the relative concentration of terrace atoms will increase, whereas small particle size favors the kink type of surface atoms.

The mechanism of homogeneous hydrogenation[462] catalyzed by $RhCl(Ph_3P)_3$ (**100**, Wilkinson's catalyst)[463] involves reaction of the catalyst with hydrogen to form a metal hydride $(PPh_3)_2RhH_2Cl$ (**106**).[464] Replacement of a triphenylphosphine ligand with two toms of hydrogen constitutes an oxidative addition.



After coordination of the alkene to form **107**, transfer of hydrogen to carbon is an insertion process, presumably generating **109**, and a second insertion liberates the hydrogenated compound, and rhodium species **108**, which adds hydrogen by oxidative addition to give **106**. Alternatively, replacement of triphenylphosphine can lead to **107**, with two hydrogen atoms and a η^2-alkene complex. If a mixture of H_2 and D_2 is used, the product contains only dideuterated and non-deuterated compounds; no mono-deuterated products are found, indicating that (unlike the case of heterogeneous catalysis) H_2 or D_2 has been added to one alkene molecule and that no exchange takes place.[330] Although conversion of **107** to the products takes place in two steps,[465] the addition of H_2 to the double bond is syn, although bond rotation in **109** can lead to stereochemical mixtures.

The occurrence of hydrogen exchange and double-bond migration in heterogeneous catalytic hydrogenation means that the hydrogenation does not necessarily

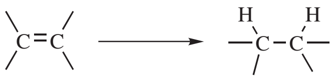
take place by straightforward addition of two hydrogen atoms at the site of the original double bond. Consequently, this method is not synthetically useful for adding D_2 to a double or triple bond in a regioselective or stereospecific manner. However, this objective can be achieved (with syn addition) by a homogeneous catalytic hydrogenation, which usually adds D_2 without scrambling[466] or by the use of one of the diimide methods (**15-12**). Deuterium can also be regioselectively added by the hydroboration–reduction procedure previously mentioned.

Reductions of double and triple bonds are found at OS **I**, 101, 311; **II**, 191, 491; **III**, 385, 794; **IV**, 298, 304, 408; **V**, 16, 96, 277; **VI**, 68, 459; **VII**, 226, 287; **VIII**, 420. 609; **IX**, 169, 533.

Catalysts and apparatus for hydrogenation are found at OS **I**, 61, 463; **II**, 142; **III**, 176, 181, 685; **V**, 880; **VI**, 1007.

15-12 Other Reductions of Double and Triple Bonds



Although catalytic hydrogenation is the method most often used, double or triple bonds can be reduced by other reagents, as well. Among these are sodium in ethanol, sodium and *tert*-butyl alcohol in HMPA,[467] lithium and aliphatic amines[468] (see also, **15-13**), zinc and acids, sodium hypophosphate and Pd—C,[469] $(EtO)_3$-$SiHPd(OAc)_2$,[470] triethylsilane Et_3SiH and trifluoroacetic acid[471] or palladium chloride,[472] and hydroxylamine and ethyl acetate.[473] Trialkylsilanes (R_3SiH) in conjunction with an acid will reduce double bonds.[474] Siloxanes (RO_3SiH) and a ruthenium catalyst, followed by treatment with AgF convert alkynes to *trans*-alkenes.[475] Poly(methylhydrosiloxane) was used for reduction of conjugated alkenes using a copper carbene complex.[476] Reduction of alkynes with silanes and a ruthenium catalyst, followed by treatment with CuI and Bu_4NF gave the

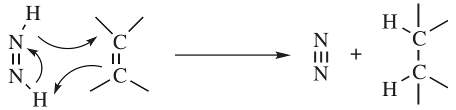
trans- alkene.[477] Samarium iodide in water and a triamine additive led to reduction of alkenes.[478] Similar reduction was reported using $Co_2(CO)_8$ and an excess of water in dimethoxyethane.[479] Reduction of an alkyne to an alkene can be done via an organometallic, by heating the alkyne with indium metal in aqueous ethanol.[480] Alkynes are reduced with palladium acetate and sodium ethoxide. In methanol the product is the alkane, whereas in THF the product is the cis-alkene.[481]

In the above-mentioned reactions with hydrazine and hydroxylamine, the actual reducing species is diimide NH=NH, which is formed from N_2H_4 by the oxidizing agent and from NH_2OH by the ethyl acetate.[482] The rate of this reaction has been studied.[483] Although both the syn and anti forms of diimide are produced, only the syn form reduces the double bond,[484] at least in part by a cyclic mechanism:[485]



The addition is therefore stereospecifically syn[486] and, like catalytic hydrogenation, generally takes place from the less-hindered side of a double bond, although not much discrimination in this respect is observed where the difference in bulk effects is small.[487] Diimide reductions are most successful with symmetrical multiple bonds (C=C, C≡C, N=N) and are not useful for those inherently polar (C≡N, C=N, C=O, etc.). Diimide is not stable enough for isolation at ordinary temperatures, although it has been prepared[488] as a yellow solid at −196°C. *N*-Arylsulfonylhydrazines bearing a phosphonate ester unit converted 1,1-diiodoalkenes ($C{=}CI_2$) to *gem*-diiodides, ($CH{-}CHI_2$).[489]

An indirect method[490] of double-bond reduction involves hydrolysis of boranes (prepared by **15-16**). Trialkylboranes can be hydrolyzed by refluxing with carboxylic

acids,[491] while monoalkylboranes, RBH_2, can be hydrolyzed with base.[492] Triple bonds can be similarly reduced, to cis alkenes.[493] Further reduction is also possible. When an alkyne was treated with decaborane and Pd/C in methanol, two equivalents of hydrogen are transferred to give the alkane.[494] Hydrogenation with Ni_2B on borohydride exchange resin (BER) has also been used.[495] Reduction occurs *in situ* when an alkene is treated with $NaBH_4$, $NiCl_2$•6 H_2O with moist alumina.[496] Reduction of alkenes occurs with *tert*-butylamine•borane complex in methanol with 10% Pd/C.[497]

Metallic hydrides, such as lithium aluminum hydride and sodium borohydride, do not in general reduce carbon–carbon double bonds, although this can be done in special cases where the double bond is polar, as in 1,1-diarylethenes[498] and in enamines.[499] Lithium aluminum hydride reduces cyclopropenes with a pendant alcohol in the allylic position to the corresponding cyclopropane.[500]

Triple bonds can also be selectively reduced to double bonds with diisobutylaluminum hydride (Dibal-H),[501] with activated zinc (see **12-38**),[502] with hydrogen and Bi_2B–borohydride exchange resin,[503] or (internal triple bonds only) with alkali metals (Na, Li) in liquid ammonia or a low-molecular-weight amine.[504] Terminal alkynes are not reduced by the Na—NH_3 procedure because they are converted to acetylide ions under these conditions. However, terminal triple bonds can be reduced to double bonds by the addition to the Na—NH_3 solution of $(NH_4)_2SO_4$, which liberates the free ethynyl group.[505] The reaction of a terminal alkyne with

lithium naphthalenide and $NiCl_2$ effectively reduced the alkyne unit (i.e., $PhC{\equiv}CH \rightarrow PhCH_2CH_3$).[506] This reagent is also effect for the reduction of simple alkenes.[507] A mixture of $NaBH_4$ and $BiCl_3$ also reduced certain alkenes[508] and An alkyne unit was reduced to an alkene, in the presence of a phenylthio group elsewhere in the molecule, using $Cp_2Zr(H)Cl$.[509]

Reduction of just one double bond of an allene, to give an alkene, has been accomplished by treatment with Na—NH_3[510] or with Dibal-H,[511] and by hydrogenation with $RhCl(PPh_3)_3$ as catalyst.[512]

When double bonds are reduced by lithium in ammonia or amines, the mechanism is similar to that of the Birch reduction (**15-13**).[513] The reduction with trifluoroacetic acid and Et_3SiH has an ionic mechanism, with H^+ coming in from the acid and H^- from the silane.[290] In accord with this mechanism, the reaction can be applied only to those alkenes, which when protonated can form a tertiary carbocation or one stabilized in some other way, for example, by a OR substitution.[514] It has been shown, by the detection of CIDNP, that reduction of α-methylstyrene by hydridopentacarbonylmanganese(I), $HMn(CO)_5$, involves free-radical addition.[515]

Catalytic hydrogenation of triple bonds and the reaction with Dibal-H usually give the cis-alkene (**15-11**). Most of the other methods of triple-bond reduction lead to the more thermodynamically stable trans alkene. However, this is not the case with the method involving hydrolysis of boranes or with the reductions with activated zinc, hydrazine, or NH_2OSO_3H, which also give the cis products.

The fact that ordinary double bonds are inert toward metallic hydrides is quite useful, since it permits reduction of, say, a carbonyl or nitro group, without disturbing a double bond in the same molecule (see Chapter 19 for a discussion of selectivity in reduction reactions). Sodium in liquid ammonia also does not reduce ordinary double bonds,[516] although it does reduce alkynes, allenes, conjugated dienes,[517] and aromatic rings (**15-13**).

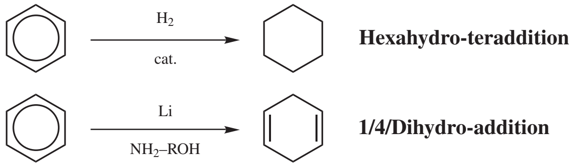
Another hydrogenation method is called *transfer hydrogenation*.[518] In this method the hydrogen comes from another organic molecule, which is itself oxidized. A transition-metal catalyst, heterogeneous or homogeneous, is frequently employed. Dendritic catalysts have been used for asymmetric transfer hydrogenation.[519] A common reducing agent is cyclohexene, which, when a palladium catalyst is used, is oxidized to benzene, losing 2 mol of hydrogen.

Enantioselective reduction of certain alkenes has also been achieved by reducing with baker's yeast.[520]

Reductions of double and triple bonds are found at OS **III**, 586, 742; **IV**, 136, 302, 887; **V**, 281, 993; **VII**, 524; **80**, 120.

15-13 Hydrogenation of Aromatic Rings



Aromatic rings can be reduced by catalytic hydrogenation,[521] but higher temperatures (100–200°C) are required than for ordinary double bonds.[522] although the reaction is usually carried out with heterogeneous catalysts, homogeneous catalysts have also been used; conditions are much milder with these.[523] Mild conditions are also successful in hydrogenations with phase transfer catalysts.[524] Hydrogenation in ionic liquids is known,[525] and also hydrogenation in supercritical ethane containing water.[526] Many functional groups, such as OH, O^-, COOH, COOR, NH_2, do not interfere with the reaction, but some groups may be preferentially reduced. Among these are CH_2OH groups, which undergo hydrogenolysis to CH_3 (**19-54**). Phenols may be reduced to cyclohexanones, presumably through the enol. Heterocyclic compounds are often reduced. Thus furan gives THF. The

nitrogen-containing ring of quinolines is reduced by hydrogenation using iodine and an iridium catalyst.[527] Catalytic hydrogenation of the five-membered ring in indole derivatives using a chiral rhodium catalyst gave hydroindoles with excellent enantioselectivity.[528]

With benzene rings it is usually impossible to stop the reaction after only one or two bonds have been reduced, since alkenes are more easily reduced than aromatic rings.[529] Thus, 1 equivalent of benzene, treated with 1 equivalent of hydrogen, gives no cyclohexadiene or cyclohexene, but $\frac{1}{3}$ equivalent of cyclohexane and $\frac{2}{3}$ equivalent of recovered benzene. This is not true for all aromatic systems. With anthracene, for example, it is easy to stop after only the 9,10-bond has been reduced (see p. 59). Hydrogenation of phenol derivatives can lead to conjugated cyclohexenones.[530] Hydrogenation of toluene in an ionic liquid using a ruthenium catalyst gave methylcyclohexane.[531]

When aromatic rings are reduced by lithium (or potassium or sodium) in liquid ammonia (such reductions are known as *dissolving metal reductions*), usually in the presence of an alcohol (often ethyl, isopropyl, or *tert*-butyl alcohol), 1,4-addition of hydrogen takes place and nonconjugated cyclohexadienes are produced.[532] This reaction is called the *Birch reduction*.[533] Heterocycles, such as pyrroles,[534] furans,[535] pyridines,[536] and indolones,[537] can be reduced using Birch reduction. Ammonia obtained commercially often has iron salts as impurities that lower the yield in the Birch reduction. Therefore it is often necessary to distill the ammonia. When substituted aromatic compounds are subjected to the Birch reduction, electron-donating groups, such as alkyl or alkoxyl decrease the rate of the reaction and are generally found on the nonreduced positions of the product. For example, anisole gives 1-methoxy-1,4-cyclohexadiene, not 3-methoxy-1,4-cyclohexadiene. On the other hand, electron-withdrawing groups, such as COOH or $CONH_2$,

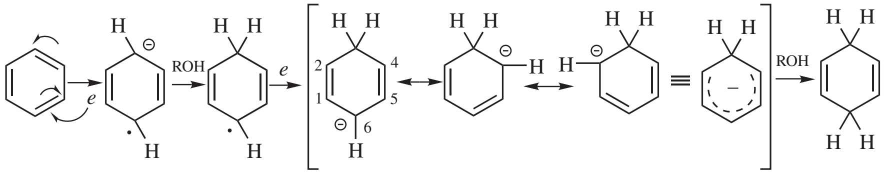
increase the reaction rate and are found on the reduced positions of the product.[538] The regioselectivity of the reaction has been examined.[539] The mechanism involves solvated electrons,[540] which are transferred from the metal to the solvent, and hence to the ring:[541]



110 **111**

The sodium becomes oxidized to Na^+ and creates a radical ion (**110**).[542] There is a great deal of evidence from ESR spectra for these species.[543] The radical ion accepts a proton from the alcohol to give a radical, which is reduced to a carbanion by another sodium atom. Finally, **111** accepts another proton. Thus the function of the alcohol is to supply protons, since with most substrates ammonia is not acidic enough for this purpose. In the absence of the alcohol, products arising from dimerization of **110** are frequently obtained. There is evidence[544] at least with some substrates, for example, biphenyl, that the radical ion corresponding to **110** is converted to the carbanion corresponding to **111** by a different pathway, in which the order of the steps is reversed: first a second electron is gained to give a dianion,[542] which then acquires a proton, producing the intermediate corresponding to **111**.

Ordinary alkenes are usually unaffected by Birch-reduction conditions, and double bonds may be present in the molecule if they are not conjugated with the ring. However, phenylated alkenes, internal alkynes (**15-12**),[545] and conjugated alkenes (with C=C or C=O) are reduced under these conditions.

Note that **111** is a resonance hybrid; that is, we can write the two additional canonical forms shown. The question therefore arises: Why does the carbanion pick up a proton at the 6 position to give the 1,4-diene? Why not at the 2 position

[538]These regioselectivities have generally been explained by molecular-orbital considerations regarding the intermediates involved. For example, see Birch, A.J.; Hinde, A.L.; Radom, L. *J. Am. Chem. Soc.* ***1980***, *102*, 3370, 4074, 6430; ***1981***, *103*, 284; Zimmerman, H.E.; Wang, P.A. *J. Am. Chem. Soc.* ***1990***, *112*, 1280. to give the 1,3-diene?[546] An answer to this question has been proposed by Hine, who has suggested that this case is an illustration of the operation of the *principle of least motion*.[547] According to this principle, "those elementary reactions will be favored that involve the least change in atomic position and electronic configuration."[547] The principle can be applied to the case at hand in the following manner (simplified): The valence-bond bond orders (p. 32) for the six carbon–carbon bonds (on the assumption that each of the three forms contributes equally) are (going around the ring) $1\frac{2}{3}$, 1, 1, $1\frac{2}{3}$, $1\frac{1}{3}$, and $1\frac{1}{3}$. When the carbanion is converted to the diene, these bond orders change as follows:

It can be seen that the two bonds whose bond order is 1 are unchanged in the two products, but for the other four bonds there is a change. If the 1,4-diene is formed, the change is $\frac{1}{3}+\frac{1}{3}+\frac{1}{3}+\frac{1}{3}$, while formation of the 1,3-diene requires a change of $\frac{1}{3}+\frac{2}{3}+\frac{2}{3}+\frac{1}{3}$. Since a greater change is required to form the 1,3-diene, the principle of least motion predicts formation of the 1,4-diene. This may not be the only factor, because the ^{13}C NMR spectrum of **111** shows that the 6 position has a somewhat greater electron density than the 2 position, which presumably would make the former more attractive to a proton.[548]

Reduction of aromatic rings with lithium[549] or calcium[550] in amines (instead of ammonia: called *Benkeser reduction*) proceeds further and cyclohexenes are obtained. It is thus possible to reduce a benzene ring, by proper choice of reagent, so that one, two, or all three double bonds are reduced.[551] Lithium triethylborohydride ($LiBEt_3H$) has also been used, to reduce pyridine derivatives to piperidine derivatives.[552]

Transition metals and metal compounds can reduce aromatic rings in the proper medium. Indium metal reduces the pyridine ring in quinoline in aqueous ethanol solution[553] as well as the C=C unit in the five-membered ring of indole

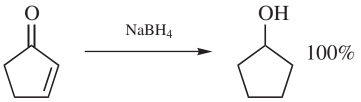
derivatives.[554] Samarium iodide (SmI_2) reduces pyridine in aq. THF[555] and phenol in MeOH/KOH.[556] Ammonium formate and a Pd—C catalyst reduces pyridine *N*-oxide to piperidine in methanol.[557] The nitrogen-containing ring of quinolines is reduced with an iridium catalyst in isopropanol.[558]

OS **I**, 99, 499; **II**, 566; **III**, 278, 742; **IV**, 313, 887, 903; **V**, 398, 400, 467, 591, 670, 743, 989; **VI**, 371, 395, 461, 731, 852, 856, 996; **VII**, 249.

15-14 Reduction Of The Double or Triple Bonds Conjugated to Carbonyls, Cyano, and so on.



In certain cases,[559] metallic hydride reagents may also reduce double bonds in conjugation with C=O bonds, as well as reducing the C=O bonds, as in the conversion of cyclopentenone to cyclopentanol.[560] The reagent $NaBH_4$ has a greater tendency than $LiAlH_4$ to effect this double reduction, although even with $NaBH_4$ the product of single reduction (of the C=O bond) is usually formed in larger amount than the doubly reduced product. Lithium aluminium hydride gives significant double reduction only in cinnamyl systems, for example, with PhCH=CHCOOH.[561] Lithium aluminium hydride also reduces the double bonds of allylic alcohols[562] and $NaBH_4$ in MeOH—THF[563] or $NaCNBH_3$ on a zeolite[564] reduces α,β-unsaturated nitro compounds to nitroalkanes. The C=C unit proximal to the carbonyl in dienyl amides is selectively reduced with $NaBH_4/I_2$.[565] Mixed hydride reducing agents, such as $NaBH_4$—$BiCl_3$,[566] $NaBH_4$—$InCl_3$,[567] borohydride exchange resin (BER)—$CuSO_4$,[568] and Dibal—$Co(acac)_2$[569] have been

used. The $InCl_3$–$NaBH_4$ reagent was used to covert conjugated diene ketones (C=C–C=C–C=O) selectively to the nonconjugated alkenyl ketone (C=C–CH_2CH_2–C=O).[570]

Note that both $LiAlH_4$ and $NaBH_4$, as well as NaH, reduce ordinary alkenes and alkynes when complexed with transition-metal salts, such as $FeCl_2$ or $CoBr_2$.[571]

Reduction of only the C=C bond of conjugated C=C–C=O and C=C–C≡N systems[572] has been achieved by many reducing agents,[573] a few of which are H_2 and a Rh catalyst,[574] a Ru catalyst,[575] a Pd catalyst,[576] or an Ir catalyst,[577] and Raney nickel alone.[578] Reagents such as SmI_2,[579] and catecholborane[580] are effective. Conjugated ketones react with 2 equivalents of Cp_2TiCl in THF/MeOH to give the corresponding saturated ketone.[581] Indium metal in aqueous ethanol with ammonium chloride converts alkylidene dimalononitriles to the saturated dinitrile.[582] Zinc and acetic acid has been used for the conjugate reduction of dihydropyridin-4-ones.[583] Formic acid with a palladium catalysts reduced conjugated carboxylic acids.[584]

Silanes can be effective for the reduction of the C=C unit in conjugated systems in the presence of copper species.[585] $PhSiH_3$ and a nickel catalyst,[586] CuCl,[587] or a manganese catalyst.[588] In addition, PhR_2SiH with a copper catalyst,[589] and

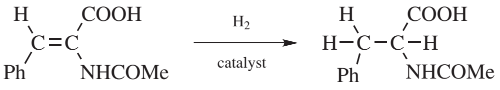
$PhSiH_3$—$Mo(CO)_6$[590] have been used. Triphenylsilane was also used for the asymmetric reduction of nitro alkenes (C=C—NO_2).[591] Poly(methylhydrosiloxane) with a chiral copper catalyst gave conjugate reduction of conjugated esters to give the saturated derivative with high enantioselectivity.[592]

A β-bromo conjugated lactone was reduced to the β-bromolactone with modest enantioselectivity using an excess of Ph_3SiH and a CuCl catalyst with a chiral ligand.[593] A copper complex with a chiral ligand and poly(methylhydrosiloxane) gave reduction of the C=C unit in conjugated carbonyl systems with good enantioselectivity.[594] Tributyltin hydride, in the presence of $MgBr_2$•OEt_2 gave 1,4-reduction of conjugated esters.[595]



(+) or (–)

112 **113**

Optically active catalysts, primarily homogeneous, have been used to achieve enantioselective hydrogenations[596] of many prochiral conjugated substrates.[597] For example,[598] hydrogenation of **112** with a suitable catalyst gives (+) or (−)

been used for conjugated acids.[613] Asymmetric hydrogenation of conjugated carboxylic acids in an ionic liquid is known using a chiral ruthenium complex[614] Enamino esters have been hydrogenated with high enantioselectivity using chiral rhodium catalysts.[615]

See **19-36** for methods of reducing C=O bonds in the presence of conjugated C=C bonds.

The C=C unit of conjugated aldehydes has been reduced using $AlMe_3$ with a catalytic amount of CuBr[616] and with ammonium formate/Pd–C.[617] Polymer-supported formate has been used for the 1,4-reduction of conjugated ketones[618] and conjugated acids using a rhodium catalyst and microwave irradiation.[619] Selective reduction of the C=C unit in conjugated ketones was accomplished with $Na_2S_2O_4$ in aqueous dioxane, and nonconjugated alkenes were not reduced.[620] Isopropanol and an iridium catalyst gives conjugate reduction of conjugated ketones.[621] Conjugate hydrostannation by an iodotin hydride ate complex, followed by hydrolysis converts unsaturated esters to saturated esters.[622] The reaction of conjugated ketones with aluminum chlorides, followed by treatment with water generates the saturated ketone.[623]

Baker's yeast reduces conjugated nitro compounds to nitroalkanes[624] and also the C=C unit of conjugated ketones.[625] Other enzymatic reductions are possible. A reductase from *Nicotiana tabacum* reduced a conjugated ketone to the saturated ketone, with excellent enantioselectivity.[626] Enzyme YNAR-I and NADP-H reduces conjugated nitro compounds to nitroalkanes.[627]

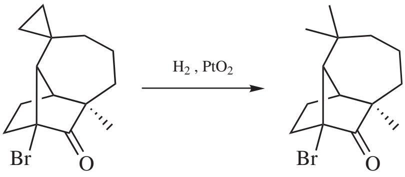
Cyclopropanes can be cleaved by catalytic hydrogenolysis.[628] Among the catalysts used have been Ni, Pd, Rh,[629] and Pt. The reaction can often be run under mild conditions.[630] Certain cyclopropane rings, especially cyclopropyl ketones and aryl-substituted cyclopropanes,[631] can be reductively cleaved by an alkali metal (generally Na or Li) in liquid ammonia.[632] Similar reduction has been accomplished photochemically in the presence of $LiClO_4$.[633] This reaction is an excellent way to introduce a *gem*-dimethyl unit into a molecule. Hydrogenation of the cyclopropane ring in **114**, for example, gave the *gem*-dimethyl unit in **115** using PtO_2 (Adam's catalyst).[634]



114 **115**

F. A Metal on the Other Side

15-16 Hydroboration

When alkenes are treated with borane[635] in ether solvents, BH_3 adds across the double bond.[636] Borane cannot be prepared as a stable pure compound[637] (it dimerizes to diborane, B_2H_6), but it is commercially available in the form of

'ate' complexes with THF, Me_2S,[638] phosphines, or tertiary amines. The alkenes can be treated with a solution of one of these complexes ($THF—BH_3$ reacts at 0°C and is the most convenient to use; $R_3N—BH_3$ generally require temperatures of ~100°C; however, the latter can be prepared as air-stable liquids or solids, while the former can only be used as relatively dilute solutions in THF and are decomposed by moisture in air) or with a mixture of $NaBH_4$ and BF_3 etherate, which generates borane *in situ*.[639] With relatively unhindered alkenes, the process cannot be stopped with the addition of one molecule of BH_3 because the resulting RBH_2 adds to another molecule of alkene to give R_2BH, which in turn adds to a third alkene molecule, so that the isolated product is a trialkylborane R_3B. The reaction can be performed on alkenes with one to four substituents, including cyclic alkenes, but when the alkene is moderately hindered, the product *is* the dialkylborane R_2BH or even the monalkylborane RBH_2.[640] For example, **116** (*disiamylborane*) and **117** (*thexylborane*)[641] have been prepared in this manner. Monoalkylboranes RBH_2 (which can be prepared from hindered alkenes, as above) and dialkylboranes R_2BH also add to alkenes, to give the mixed trialkylboranes RR'_2 B and $R_2R'B$, respectively. Surprisingly, when methylborane $MeBH_2$,[642] which is not a bulky molecule, adds to alkenes in the solvent THF, the reaction can be stopped with one addition to give the dialkylboranes RMeBH.[643] Reaction of this with a second alkene produces the trialkylborane RR'MeB.[644] Other monoalkylboranes, *i*$PrBH_2$, *n*-$BuBH_2$, *s*-$BuBH_2$, and *t*-$BuBH_2$, behave similarly with internal alkenes, but not with alkenes of the type $RCH{=}CH_2$.[645]

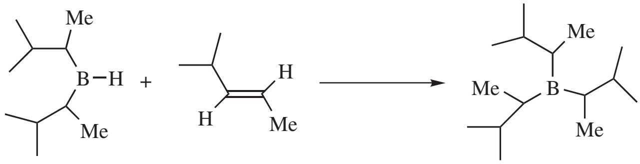
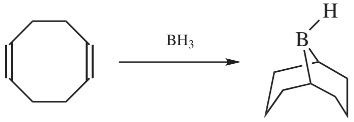
In all cases, the boron goes to the side of the double bond that has more hydrogens, whether the substituents are aryl or alkyl.[646] This actually follows Markovnikov's rule, since boron is more positive than hydrogen. However, the regioselectivity is caused mostly by steric factors, although electronic factors also play a part. Studies of the effect of ring substituents on rates and on the direction of attack in hydroboration of substituted styrenes showed that the reaction with boron and the alkene has electrophilic character.[647] When both sides of the double bond are monosubstituted or both disubstituted, about equal amounts of each isomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large borane molecule. For example, treatment of *i*PrCH=CHMe with borane gave 57% of product with boron on the methyl-bearing carbon and 43% of the other, while treatment with **116** gave 95% **118** and only 5% of the other isomer.[648]



116 **118**

Another reagent with high regioselectivity is 9-borabicyclo[3.3.1]nonane (9-BBN), which is prepared by hydroboration of 1,5-cyclooctadiene,[649] and has the advantage that it is stable in air. Borane is quite unselective and attacks all sorts of double bonds. Disiamylborane, 9-BBN, and similar molecules are far more selective and preferentially attack less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one alkene in the presence of a less reactive alkene.[650] For example, 1-pentene can be removed from a mixture of 1- and 2-pentenes, and a cis alkene can be selectively hydroborated in a mixture of the cis and trans isomers.



9-BBN

For most substrates, the addition in hydroboration is stereospecific and syn, with attack taking place from the less-hindered side.[651] Note that organoboranes can be analyzed using ^{11}B nmr.[652] The mechanism[653] may be a cyclic four-center one:[654]

When the substrate is an allylic alcohol or amine, the addition is generally anti,[655] although the stereoselectivity can be changed to syn by the use of catecholborane and the rhodium complexes mentioned above.[656] Because the mechanism is different, use of this procedure can result in a change in regioselectivity as well, for example, styrene $PhCH{=}CH_2$ gave $PhCH(OH)CH_3$.[657]

Monochloroborane[658] BH_2Cl coordinated with dimethyl sulfide shows greater regioselectivity than BH_3 for terminal alkenes or those of the form $R_2C{=}CHR$, and the hydroboration product is a dialkylchloroborane R_2BCl).[659] For example, 1-hexene gave 94% of the anti-Markovnikov product (the boron is on the less substituted carbon) with BH_3—THF, but 99.2% with BH_2Cl—SMe_2. Treatment of alkenes with dichloroboranedimethyl sulfide $BHCl_2$—SMe_2 in the presence of BF_3[660] or with BCl_3 and Me_3SiH[661] gives alkyldichloroboranes $RBCl_2$. Extensions of this basic approach are possible with dihalo alkylboranes. The reaction of an alkene with allyl dibromoborane, incorporated an allyl group and the born on adjacent carbons.[662]

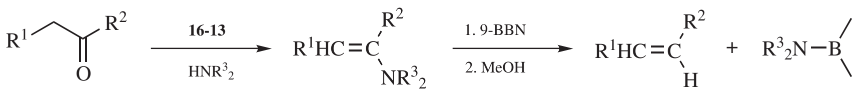
An important use of the hydroboration reaction is oxidation of an organoborane to alcohols with hydrogen peroxide and NaOH (**12-27**). Organoboranes have been oxidized with Oxone®[663] and methanol/triethylamine/molecular oxygen.[664] The synthetic result is an indirect way of adding H_2O across a double bond in an anti-Markovnikov manner. However, boranes undergo many other reactions as well. Among other things, they react with α-halo carbonyl compounds to give alkylated products (**10-73**), with α,β-unsaturated carbonyl compounds to give Michael-type addition of R and H (**15-27**), with CO to give alcohols and ketones (**18-23–18-24**); they can be reduced with carboxylic acids, providing an indirect method for reduction of double bonds (**15-11**), or they can be oxidized with chromic acid or pyridinium chlorochromate to give ketones[665] or aldehydes (from terminal alkenes),[666] dimerized with silver nitrate and NaOH (**14-26**), isomerized (**18-11**), or converted to amines (**12-32**), halides (**12-31**), or carboxylic acids.[667] They are thus useful intermediates for the preparation of a wide variety of compounds. Intramolecular hydroboration reaction are possible.[668]

Such functional groups as OR, OH, NH_2, SMe, halogen, and COOR may be present in the molecule,[669] but not groups that are reducible by borane. Hydroboration of enamines with 9-BBN provides an indirect method for reducing an aldehyde or ketone to an alkene, e.g.[670]



Enamines can also be converted to amino alcohols via hydroboration.[671] Allene–boranes react with aldehydes to give alkyne–alcohols.[672]

Use of the reagent diisopinocampheylborane **119** (prepared by treating optically active α-pinene with BH_3) results in enantioselective hydroboration–oxidation.[673] Since both (+) and (−) α-pinene are readily available, both enantiomers

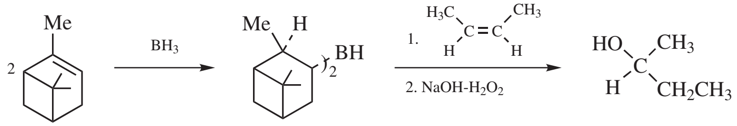
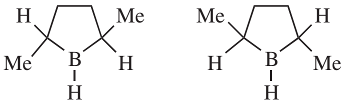
can be prepared. Alcohols with moderate-to-excellent enantioselectivities have been



α-Pinene Optically active 119 Optically active

obtained in this way.[674] However, **119** does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane[675] although optical yields are lower. Limonylborane,[676] 2- and 4-dicaranylboranes,[677] a myrtanylborane,[678] and dilongifolylborane[679] have also been used. Other new asymmetric boranes have also been developed. The chiral cyclic boranes *trans*-2,15-dimethylborolanes (**51** and **52**) also add enantioselectively to alkenes (except



(*R*, *R*) **120** **121** (*S*, *S*)

alkenes of the form RR′C=CH$_2$) to give boranes of high optical purity.[680] When chiral boranes are added to trisubstituted alkenes of the form RR′C=CHR″, two new chiral centers are created, and, with **120** or **121**, only one of the four possible diastereomers is predominantly produced, in yields $> 90\%$.[680] This has been called *double-asymmetric synthesis*.[681] An alternative asymmetric synthesis of alcohols involves the reaction of catechol borane with an alkene in the presence

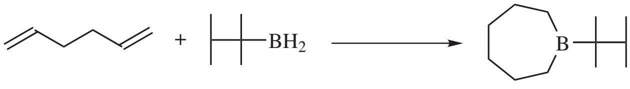
[681]For another enantioselective hydroboration method, see p. 1082.

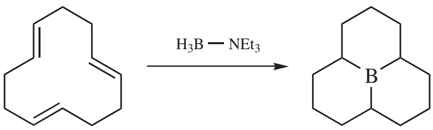
of a chiral rhodium catalyst, giving the alcohol enantioselectivity after the usual oxidation.[682]

The double bonds in a conjugated diene are hydroborated separately, that is, there is no 1,4-addition. However, it is not easy to hydroborate just one of a conjugated system, since conjugated double bonds are less reactive than isolated ones. Thexylborane[641] (**117**) is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated, as in the formation of **122**.[683]



48 **122**

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with BH_3 itself.[684] One example is the formation of 9-BBN, shown above. Another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene, **123**.[685] If a diene is treated with a diaminoborane and a samarium catalyst, oxidation leads to a carbocyclic ring with a pendant hydroxymethyl group.[686]



123

Triple bonds[687] can be monohydroborated to give vinylic boranes, which can be reduced with carboxylic acids to cis-alkenes or oxidized and hydrolyzed to aldehydes or ketones. Terminal alkynes give aldehydes by this method, in contrast to the mercuric or acid-catalyzed addition of water discussed at **15-4**. However, terminal alkynes give vinylic boranes[688] (and hence aldehydes) only when treated with a hindered borane, such as **116**, **117**, or catecholborane (p. 820),[689] or with $BHBr_2$—SMe_2.[690] The reaction between terminal alkynes and BH_3 produces

1,1-dibora compounds, which can be oxidized either to primary alcohols (with NaOH—H_2O_2) or to carboxylic acids (with *m*-chloroperoxybenzoic acid).[691] Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.[692] On the other hand, dimesitylborane selectively hydroborates triple bonds in the presence of double bonds.[693] Furthermore, it is often possible to hydroborate selectively one particular double bond of a nonconjugated diene.[694] A triple bond can be hydroborated in the presence of a ketone, and treatment with acetic acid reduces the C≡C unit to a cis- alkene (see **15-12**).[695] When the reagent is catecholborane, hydroboration is catalyzed by rhodium complexes,[696] such as Wilkinson's catalyst,[697] by SmI_2,[698] or lanthanide reagents.[699] Enantioselective hydroboration–oxidation has been achieved by the use of optically active rhodium complexes.[700]

A chain extension variation involved the reaction of styrene with catecholborane and then Me_3SiCHN_2.[701] Subsequent oxidation with NaOH/H_2O_2 and the reaction with Bu_4NF gave 3-phenyl-1-propanol.

An unusual extension of hydroboration involves remote C—H activation. Aryl alkenes are treated with borane and then oxidized in the usual manner. The product is a phenol and a hydroxymethyl group (Ph—C=C—CH_3 → *o*-Ph—CH—CH—CH_2OH.[702]

Ar_3SnH) add to double bonds to give organometallic compounds.[703] The hydroboration reaction (**15-16**) is the most important example, but other important metals in this reaction are aluminum,[704] tin,[705] and zirconium[706] [a Group 4 (IV B) metal]. Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.[707] Hydrozirconation is most commonly carried out with Cp_2ZrHCl (Cp = cyclopentadienyl),[708] known as *Schwartz's reagent*. The mechanism with Group 13 (III A) hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with Group 14 (IV A) hydrides a mechanism involving free radicals seems more likely. Dialkylmagnesium reagents have been obtained by adding MgH_2 to double bonds.[709] With Grignard reagents such as RMgX, the Grignard reagent can be added to an alkene $R'CH{=}CH_2$ to give $R'CH_2CH_2MgX$, with $TiCl_4$ as a catalyst.[710] With some reagents triple bonds[711] can add 1 or 2 equivalents, to give **124** or **125**.[712]

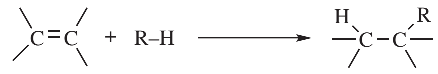
G. Carbon or Silicon on the Other Side

15-18 Addition of Alkanes

Hydro-alkyl-addition



There are two important ways of adding alkanes to alkenes: the thermal and the acid-catalysis method.[713] Both give chiefly mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method the reactants are heated to high temperatures (~500°C) at high pressures (150–300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.[714] The mechanism is undoubtedly of a free-radical type and can be illustrated by one possible sequence in the reaction between propane and ethylene:

$$\text{Step 1}\quad CH_3CH_2CH_3 + CH_2{=}CH_2 \xrightarrow{\Delta} CH_3{-}\dot{C}H{-}CH_3 + CH_3CH_2\bullet$$

$$\text{Step 2}\quad CH_3{-}\dot{C}H{-}CH_3 + CH_2{=}CH_2 \longrightarrow (CH_3)_2CHCH_2CH_2\bullet$$

$$\text{Step 3}\quad (CH_3)_2CHCH_2CH_2\bullet + CH_3CH_2CH_3 \longrightarrow (CH_3)_2CHCH_2CH_3 + CH_3\dot{C}HCH_3$$

There is kinetic evidence that the initiation takes place primarily by steps like 1, which are called *symproportionation* steps[715] (the opposite of disproportionation, p. 280).

In the acid-catalysis method, a proton or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between −30 and 100°C. This is a Friedel–Crafts process with a carbocation mechanism[716] (illustrated for a proton

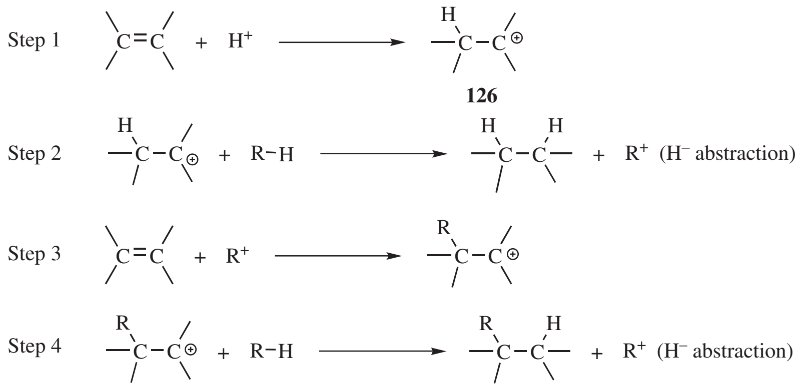
acid catalyst):



127

Carbocation **127** often rearranges before it abstracts a hydride, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. It is also possible for **126** (or **127**) instead of abstracting a hydride, to add to another mole of alkene, so that not only rearrangement products but also dimeric and polymeric products are frequent. If the tri- or tetrasubstituted alkenes are treated with Me_4Si, HCl, and $AlCl_3$, they become protonated to give a tertiary carbocation, which reacts with the Me_4Si to give a product that is the result of addition of H and Me to the original alkene.[717] (For a free-radical hydromethyl-addition, see **15-28**.) Addition a cation to a vinyl bromide, generated from an α-ethoxy-lactam with trifluoroacetic acid, generated a ketone.[718] An intramolecular cyclization of 1-dodecene to cyclododecane was reported using aluminum chloride in an ionic liquid.[719]

Alkanes add to alkynes under photolysis conditions to give an alkene.[720] Tetrahydrofuran adds to alkynes to give the alkene with microwave irradiation.[721]

The reaction can also be base catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.[722] Carbanions most often used are those stabilized by one or more α-aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane:[723]

$$PhCH_3 \xrightarrow{Na} Ph\overset{\ominus}{C}H_2 + PhCH{=}CH_2 \longrightarrow Ph\overset{\ominus}{C}H{-}CH_2CH_2Ph \xrightarrow{solvent} PhCH_2CH_2CH_2Ph$$

Conjugated dienes give 1,4-addition.[724] This reaction has also been performed with salts of carboxylic acids in what amounts to a method of alkylation of carboxylic acids[725] (see also, **10-59**).

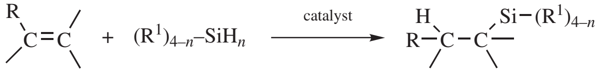
$$CH_3COOK \xrightarrow{NaNH_2} {}^{\ominus}CH_2COOK + CH_2{=}CH_2 \longrightarrow {}^{\ominus}CH_2{-}CH_2CH_2COOK$$

There are transition-metal catalyzed addition reaction of alkyl units to alkenes,[726] often proceeding with metal hydride elimination to form an alkene. An intramolecular cyclization reaction of an *N*-pyrrolidino amide alkene was reported using an iridium catalyst for addition of the carbon α to nitrogen to the alkene unit.[727]

OS **I**, 229; **IV**, 665; **VII**, 479.

15-19 Addition of Silanes

Silyl-hydro-addition



Although silanes bearing at least one Si—H unit do not generally react with alkenes or alkynes, in the presence of certain catalyst addition occurs to give the corresponding alkyl or vinyl silane. The reaction of an alkene with an yttrium,[728] ruthenium,[729] rhodium,[730] palladium,[731] lanthanum,[732] platinum[733], or samarium[734] catalyst addition occurs with high anti-Markovnikov selectivity. Silanes add to dienes with a palladium catalyst, and asymmetric induction is achieved by using a binapthyl additive.[735] Alkenes react with Li-(0) and *t*-Bu_2SiCl_2 to give a three-membered ring silane.[736] In the presence of BEt_3, silanes add to alkynes to give the corresponding vinyl silane[737] or to alkenes to give the alkylsilane, with

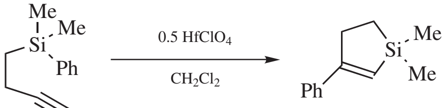
anti-Markovnikov selectivity.[738] Similar selectivity was observed when a silylated zinc reagent was added to a terminal alkyne.[739] Silanes add to alkynes to give a vinyl silane using Cp_2TiCl_2–*n*-butyllithium.[740] Siloxanes such as $(RO)_3SiH$ add to alkynes with a ruthenium catalyst to give the corresponding vinyl silane.[741] The reaction of Cl_2MeSiH and terminal alkynes, in ethanol–triethylamine with a ruthenium catalyst, to give primarily the Markovnikov vinyl silane.[742] However, Et_3SiH adds to terminal alkynes with a rhodium[743] or a platinum[744] catalyst to give the anti-Markovnikov vinyl silane. Using 0.5 equivalent of $HfClO_4$ with alkynes bearing a dimethylphenylsilyl unit gave a cyclic vinyl silane with transfer of the phenyl group to carbon (see **128**).[745] Dienes react with zirconium compounds and silanes to produce cyclic compounds in which the silyl group has also added to one C=C unit.[746] With an yttrium catalyst, $PhSiH_3$ reacts with nonconjugated dienes to give cyclic alkenes with a pendant CH_2SiH_2Ph group.[747] Rhodium compounds allow silanes to add to enamides to give the α-silylamide.[748] Allylsilanes add to certain allylic alcohols in the presence of Me_3SiOTf, via a S_N2'-like reaction, to give dienes.[749] Note that silanes open cyclopropane rings in the presence of 20% $AlCl_3$ to give the alkylsilane.[750] Formation of silanes via reaction with alkenes can be followed by reaction with fluoride ion and then oxidation to give an alcohol[751] (see **10-16**).



128

Silanes also add to alkenes under radical conditions (using AIBN) with high anti-Markovnikov selectivity.[752] An alternative route to alkylsilanes reacted an alkene with lithium metal in the presence of 3 equivalents of chlorotrimethylsilane, giving bis-1,2-trimethylsilyl compounds after treatment with water.[753] Silanes also

add to alkenes to form anti-Markovnikov alkylsilane (R_3Si—C—C—R′) in the presence of a hyponitrite.[754]

Vinyl silanes add to conjugated carbonyl compounds in the presence of a ruthenium catalyst,[755] or to acrylonitriles with a cobalt catalyst.[756] Silyl phosphines react with conjugated ynones directly to give an enone with an α-trimethylsilyl and a β-phosphine group.[757] Siloxanes of the type $(RO)_3SiH$ add to the α-carbon of enamines in the presence of a dirhodium catalyst.[758] The uncatalyzed reaction of trimethylsilyl cyanide and ynamines, however, gave an enamine with a β-trimethylsilyl and an α-cyano group.[759]

15-20 Addition of Alkenes and/or Alkynes to Alkenes and/or Alkynes

Hydro-alkenyl-addition

$$CH_2{=}CH_2 + CH_2{=}CH_2 \xrightarrow{H^+} CH_2{=}CHCH_2CH_3$$

With certain substrates, alkenes can be dimerized by acid catalysts, so that the product is a dimer that contains one double bond.[760] A combination of zinc and a $CoCl_2$ catalyst accomplished the same type of coupling.[761] One alkene adds to another in the presence of a nickel catalyst.[762] Coupling conjugated alkenes with vinyl esters to give a functionalized conjugated diene is known, using a complex palladium–vanadium catalyst in an oxygen atmosphere.[763] This reaction is more often carried out internally, as in the formation of cyclohexene **129**. A palladium catalyzed cyclization is known, in which dienes are converted to cyclopentene derivatives such as **130**.[764] Ring-forming reactions with heterocyclic compounds such as indoles are known using $PtCl_2$.[765] A ruthenium catalyzed version of this reaction gave the five-membered ring with an exocyclic double bond.[766] Carbocyclization of an alkene unit to another alkene unit was reported

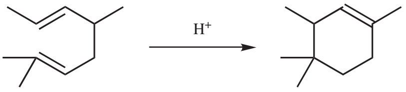
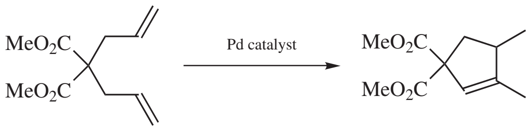
using an yttrium catalyst,[767] or a titanium catalyst.[768] In some cases, internal coupling of two alkenes can form larger rings.[769] Variations include treatment of similar dienes with $HSiMe_2OSiMe_3$ and KF-acetic acid to give a cyclopentane with a pendant trimethylsilylmethyl group trans to a methyl.[770] Exo-dig carbocyclization was reported using $HfCl_4$[771] palladium,[772] or titanium,[773] catalysts. Alkynes also add to alkenes for form rings in the presence of a palladium,[774] rhodium,[775] ruthenium,[776] iridium,[777] or a zirconium catalyst.[778] Alkene allene substrates were cyclized to form cyclic products with an exocyclic double bond using a palladium catalyst.[779] An interesting variation adds a silyl enol ether to an alkyne using $GaCl_3$ to give an unconjugated ketone (O=C–C–C=C).[780] Alkenes and alkynes can also add to each other to give cyclic products in other ways (see **15-63** and **15-65**).



129



130

Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes. For example, squalene 2,3-oxide is converted by enzymatic

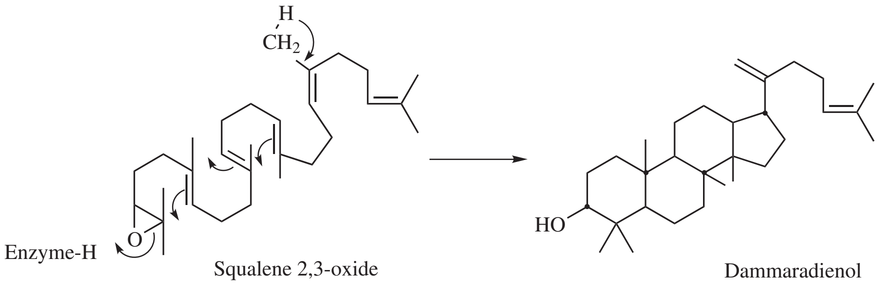
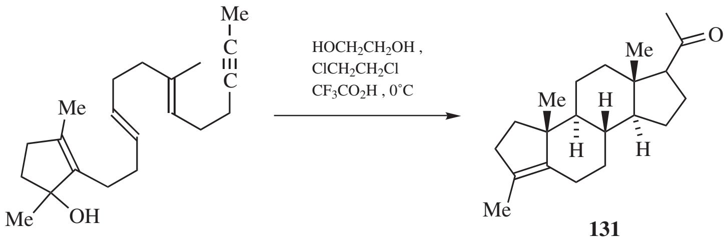
catalysis to dammaradienol.



The squalene → lanosterol biosynthesis (which is a key step in the biosynthesis of cholesterol) is similar. The idea that the biosynthesis of such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork–Eschenmoser hypothesis*.[781] Such reactions can also be carried out in the laboratory, without enzymes.[782] By putting cation-stabilizing groups at positions at which positive charges develop, Johnson and co-workers have been able to close as many as four rings stereoselectively and in high yield, in one operation.[783] An example is formation of **131**,[784] also known as the *Johnson polyene cyclization*.[785]



131

Lewis acids can be used to initiate this cyclization,[786] including $EtAlCl_2$ used for the coupling of an alkyne and an alkene.[787] Cyclization to a tricyclic systems that included formation of a dihydropyran ring was reported using mercuric

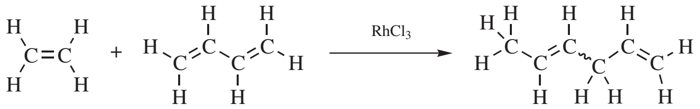
bis(trifluorosulfonate) as an initiator.[788] A radical cyclization approach (**15-30**) to polyene cyclization using a seleno-ester anchor gave a tetracyclic system.[789]

The addition of alkenes to alkenes[790] can also be accomplished by bases.[791] Coupling reactions can occur using catalyst systems[792] consisting of nickel complexes and alkylaluminum compounds (known as *Ziegler catalysts*),[793] rhodium catalysts,[794] and other transition-metal catalysts, including iron.[795] The 1,4-addition of alkenes to conjugated dienes to give nonconjugated dienes[796] occurs with various transition-metal catalysts.



and the dimerization of 1,3-butadienes to octatrienes.[797] Ethylene adds to alkenes to form a new alkene in the presence of a nickel catalyst[798] or a zirconium catalyst,[799] to alkynes in the presence of a ruthenium catalyst[800] to form a diene, and allenes add to alkynes to give a diene with a titanium catalyst.[801]

In the presence of cuprous chloride and ammonium chloride, acetylene adds to another molecule of itself to give vinylacetylene.

$$HC{\equiv}CH \; + \; HC{\equiv}CH \xrightarrow[NH_4Cl]{CuCl} HC{\equiv}C{-}CH{=}CH_2$$

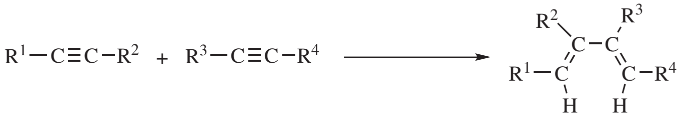
This type of alkyne dimerization is also catalyzed by nickel,[802] palladium,[803] lutetium,[804] and ruthenium catalysts.[805] Similar products are obtained by the cross-coupling an terminal alkynes with allene, using a combination of palladium and CuI catalysts.[806] The reaction has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.[807] Diynes have also been cyclized to form cyclic enynes (an endocyclic double bond) using a diruthenium catalyst with ammonium tetrafluoroborate in methanol.[808] Enynes are similarly cyclized to cyclic alkenes with an endocyclic C=C unit, analogous to formation of **200** above, using a dicobalt catalyst.[809] A molecule containing two distal conjugated diene units was cyclized to give a bicyclic molecule with an exocyclic double bond using a palladium catalyst.[810] A nickel catalyst converted a similar system to a saturated five-membered ring containing an allylic group and a vinyl group.[811]

In another type of alkyne dimerization is the reductive coupling in which two molecules of alkyne, the same or different, give a 1,3-diene.[812]



In this method, one alkyne is treated with Schwartz's reagent (see **15-17**) to produce a vinylic zirconium intermediate. Addition of MeLi or MeMgBr, followed by the second alkyne, gives another intermediate, which, when treated with aqueous acid, gives the diene in moderate-to-good yields. The stereoisomer shown is the one formed in usually close to 100% purity. If the second intermediate is treated with I_2 instead of aqueous acid, the 1,4-diiodo-1,3-diene is obtained instead, in comparable yield and isomeric purity. The reaction of alkynes with two equivalents of trimethylsilyldiazomethane and a ruthenium catalyst gave a conjugated diene with trimethylsilyl groups at C-1 and C-4.[813] Alkynes can also be coupled to allylic silyl ethers with a ruthenium catalysts to give dienes.[814] Other alkyne–allylic coupling reactions are known to give dienes.[815]

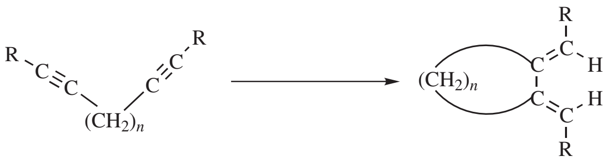
This reaction can also be done intramolecularly, as in the cyclization of diyne **132** to (*E*,*E*)-exocyclic dienes **133** by treatment with a zirconium,[816] rhodium,[817] or platinum complex.[818] A similar reaction was reported using a titanium catalyst from a diyne amide.[819]



132 **133**

Rings of four, five, and six members were obtained in high yield; seven-membered rings in lower yield. When the reaction is applied to enynes, compounds similar to **133** are formed using various catalysts, but with only one double bond[820] Internal coupling of alkene–allenes and a rhodium catalyst give similar products bearing a pendant vinyl group.[821] With a $PtCl_2$ catalyst, ring closure leads to a diene in some cases.[822] Larger rings can be formed from the appropriate enyne, including forming cyclohexadiene compounds.[823] Spirocyclic compounds can be prepared from enynes in this manner using formic acid and a palladium catalyst.[824] Enynes can also be converted to bicyclo[3.1.0]hexenes[825] or nonconjugated cyclohexadienes[826] using a gold catalyst. Internal coupling of an alkyne and a vinylidene cyclopropane unit with a palladium catalyst leads to a cyclopentene derivative with an exocyclic double bond.[827] Enynes having a conjugated alkene unit also undergo this reaction

in the presence of $ZnBr_2$.[828] Using mercury (II) triflate in water, cyclization leads to five-membered rings having an exocyclic double bond, and a pendant alcohol group.[829] Enynes give cyclic compounds with an endocyclic double bond conjugated to another alkene unit (a conjugated diene) when treated with $GaCl_3$[830] or a platinum catalyst in an ionic liquid.[831] Allene–alkenes give a similar product with a palladium catalyst[832] or a ruthenium catalyst,[833] as do alkyne–allenes with a dirhodium catalyst.[834] Ethers having an enyne unit (propargylic and allylic) give dihydrofurans upon treatment with $Co_2(CO)_8$.[835] Amines and sulfonamides bearing two propargyl groups cyclize with a ruthenium catalyst to give the corresponding dihydropyrrole.[836]

There are many useful variations. Internal coupling of an alkyne with a vinyl halide, using triethylsilane and a palladium catalyst, gave the saturated cyclic compound with two adjacent exocyclic double bonds (a 2,3-disubstituted diene.[837] Alkynes can added to propargyl acetates using palladium catalyst to give an alkyne allene.[838] Two-Substituted malonate esters having a distal alkyne unit generated vinylidene cycloalkanes when treated with a catalytic amount of *n*-butyllithium.[839] Intramolecular coupling of alkenes and allylic sulfides using *tert*-butoxide/*n*-butyllithium, and then LiBr leads to a bicyclic compound containing a fused cyclopropane ring.[840] The reaction of an alkyne with a vinyl iodide and silver carbonate, with a palladium catalyst, gave a fulvene.[841] The reaction of a terminal alkyne and a vinyl cyclopropane, with a dirhodium catalyst, gives a cycloheptadiene.[842] Alkyne–alkenes were formed by coupling terminal alkynes and allenes in the presence of a palladium catalyst.[843] An alkyne was coupled internally to an allene using a palladium catalyst, with an exocyclic methylene

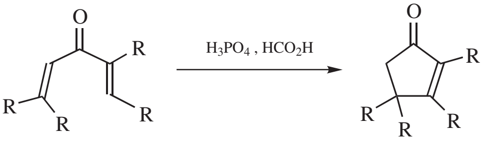
group trapped and a vinyltin derivative.[844] A similar process occurred with a rhodium catalyst, $RhCl(PPh_3)_3$, to incorporate a vinyl chloride.[845] Allene–allylic halide systems reacted with phenylboronic acid and a palladium catalyst to give cyclopentane rings with two pendant vinyl groups, one of which contained a phenyl group.[846]

In another reductive coupling, substituted alkenes ($CH_2{=}CH{-}Y$; Y =R, COOMe, OAc, CN, etc.) can be dimerized to substituted alkanes CH_3CHY-$CHYCH_3$ by photolysis in an H_2 atmosphere, using Hg as a photosensitizer.[847] Still another procedure involves palladium-catalyzed addition of vinylic halides to triple bonds to give 1,3-dienes.[848]



134 **135**

An important cyclization procedure involves acid-catalyzed addition of diene-ketones, such as **134**, where one conjugated alkene adds to the other conjugated alkene to form cyclopentenones (**135**). This is called the *Nazarov cyclization*.[849] Structural variations are possible that prepare a variety of cyclopentenones. When one of the C=C units is a vinyl ether, a cyclopentenone is formed with an oxygen attached to the alkenyl carbon.[850] Substituents on the C=C units, including $-CO_2Et$, lead to cyclopentenones that bear those substituents. The use of such a substrate with $AgSbF_6$, $CuBr_2$ and a chiral ligand gave the cyclopentenone with modest enantioselectivity.[851] Cyclization can also give the nonconjugated five-membered ring.[852] A reductive Nazarov cyclization was reported using $BF_3{\bullet}OEt_2$ and Et_3SiH, giving a cyclopentanone rather than a cyclopentenone.[853] A palladium catalyzed reaction that is related to the Nazarov cyclization converts terminal

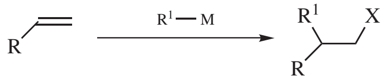
alkynes to fulvenes.[854] Note that a *retro*-Nazarov is possible with α-bromocyclopentanones.[855] In one variation using a aluminum complex, a cyclohexenone was formed.[856]

OS **VIII**, 190, 381, 505; **IX**, 310.

15-21 Addition of Organometallics to Double and Triple Bonds Not Conjugated to Carbonyls

Hydro-alkyl-addition



Neither Grignard reagents nor lithium dialkylcopper reagents generally add to ordinary C=C double bonds.[857] An exception is the reaction of $(PhMe_2Si)_2Cu(CN)Li$ to 8-oxabicyclo[3.2.1]oct-2-ene derivatives.[858] Grignard reagents usually add only to double bonds susceptible to nucleophilic attack, (e.g., fluoroalkenes and tetracyanoethylene).[859] However, active Grignard reagents (benzylic, allylic) also add to the double bonds of allylic amines,[860] and of allylic and homoallylic alcohols,[861] as well as to the triple bonds of propargyl alcohols and certain other alkynols.[862] Grignard reagents also add to alkynes in the presence of $MnCl_2$ at 100°C[863] and to alkenes in the presence of zirconium[864] or nickel[865] catalysts. It is likely that cyclic intermediates are involved in these cases, in which the magnesium coordinates with the heteroatom. Allylic, benzylic, and tertiary alkyl Grignard reagents also add to 1-alkenes and strained internal alkenes (e.g., norbornene), if the reaction is carried

out in a hydrocarbon solvent, such as pentane rather than ether, or in the alkene itself as solvent, heated, under pressure if necessary, to 60–130°C.[866] Yields are variable. *Intramolecular* addition of RMgX to completely unactivated double and triple bonds has been demonstrated.[867] The reaction of tosylates bearing a remote alkene unit and a Grignard reagent leads to cyclization when a zirconium catalyst is used.[868] The intramolecular addition of a CH_2Br unit to the C=C unit of an allylic ether was accomplished using PhMgBr and a cobalt catalyst, give a functionalized tetrahydrofuran and incorporation of the phenyl group on the C=C unit as well.[869] Grignard reagents add to the C=C unit of $(MeO)_2CRCH{=}CH{-}R$ moieties to give a 3-alkyl substituted ketone with good enantioselectivity using a nickel catalyst and a chiral additive.[870] In a useful variation, vinyl epoxides react with Grignard reagents and CuBr to give an allylic alcohol via reaction at the C=C unit and concomitant opening of the epoxide.[871] Conjugated dienes react with arylmagnesium halides, Ph_3SiCl and a palladium catalyst to give a coupling product involving the reaction of two equivalents of the diene and incorporation of two $SiPh_3$ units.[872]

Organolithium reagents (primary, secondary, and tertiary alkyl and in some cases aryl) also add to the double and triple bonds of allylic and propargylic alcohols[873] (in this case tetramethylethylenediamine is a catalyst) and to certain other alkenes containing hetero groups, such as OR, NR_2, or SR. Addition of butyllithium to alkenes has been observed with good enantioselectivity when sparteine was added.[874] Mixing an organolithium reagent with transition metal compounds, such as $CeCl_3$[875] or $Fe(acac)_3$[876] leads to addition of the alkyl group. The intramolecular addition of RLi and R_2CuLi has been reported.[877] Organolithium reagents

containing an alkene[377,878] or alkyne[879] unit cyclize[880] at low temperatures and quenching with methanol replaces the new C—Li bond with C—H. Cyclopropane derivatives have been formed in this manner.[881] Alkyllithium and alkenyllithium derivatives containing an ester moiety can be cyclized.[882] Tandem cyclization are possible with dienes and enynes to form more than one ring,[883] including bicyclic compounds.[884] Tandem cyclization is possible with alkyne iodides[885] or alkynes with a homoallylic CH_2Li unit.[886] The organolithium reagents can contain heteroatoms, such as nitrogen elsewhere in the molecule, and the organolithium species can be generated from an intermediate organotin derivative.[887] Organolithium reagents add to the less substituted C=C unit of conjugated dienes.[888] The organolithium compound can be generated *in situ* by reaction of an organotin compound with butyllithium, allowing cyclization of occur upon treatment with an excess of LiCl.[889]

Ketones with an α-hydrogen add to alkenes, intramolecular, when heated in a sealed tube with $CuCl_2$ and a palladium catalyst.[890] A similar reaction was reported using $Yb(OTf)_3$ and a palladium catalyst.[891] Keto esters add to alkynes using 10% benzoic acid and a palladium catalyst,[892] or an indium catalyst.[893] 1,3-Diketones add to dienes (1,4-addition) using a palladium catalyst,[894] a $AuCl_3$/AgOTf catalyst,[895] and this addition has been done intramolecularly using 2.4 equivalents of $CuCl_2$ and a palladium catalyst.[896] A related cyclization reaction was reported for diesters having a remote terminal alkyne unit in the molecule, with a palladium

catalyst.[897] The intermolecular addition of diesters, such as malonates, to alkynes was accomplished in acetic acid and a palladium catalyst under microwave irradiation.[898] Enolate anions can add to allylic sulfides, forming β-lactams in some cases.[899] α-Potassio amines (from an *N*-Boc amine and KHMDS) undergoes intramolecular cyclization with an alkene unit to form a dihydropyrrole.[900] The enolate anion derived from the reaction of a nitrile with potassium *tert*-butoxide added to the less substituted carbon of the C=C unit of styrene in DMSO.[901] Similarly, the intramolecular addition of a nitrile enolate (from treatment with CsOH in *N*-methylpyrrolidinone) to an alkyne gave a cyclized product with an exocyclic methylene unit.[902] Silyl enol ethers add to alkynes using a tungsten catalyst.[903] Malonate derivatives add to alkenes in the presence of an $Al(OR)_3$ catalyst.[904]

Unactivated alkenes or alkynes[905] can react with other organometallic compounds under certain conditions. Trimethylaluminum reacts with 4-methyl-1-pentene, in the presence of Cl_2ZrCp_2, for example, and subsequent reaction with molecular oxygen leads to (2*R*),4-dimethyl-1-pentanol in good yield and 74% ee.[906] These reagents also add to alkynes.[907] Aluminum chloride mediated cyclization of α-iodo ketones to a pendant alkyne unit, in the presence of ICl, gave the spirocyclic ketone with an exocyclic C=CHI unit.[908] Isopropylchloroformate (*i*PrO_2CCl) reacts with an alkene, in conjunction with $Et_3Al_2Cl_3$, to add an isopropyl group.[909] Ruthenium catalysts have been used to add allylic alcohols to alkynes.[910] Samarium iodide (SmI_2) induces cyclization of a halide moiety to an alkyne unit[911] or an alkene unit[912] to form cyclized products. Copper complexes can catalyze similar cyclization to alkenes, even when an ester unit is present in the molecule.[913] The reaction of a dithioketal containing a remote alkene moiety, with a titanium complex, leads to cyclization and incorporation of an endocyclic C=C unit in the final product.[914] Allyl manganese compounds add to allenes to give nonconjugated dienes.[915]

Vinyl halides add to allylic amines in the presence of $Ni(cod)_2$ where cod = 1, 5-cyclooctodine, followed by reduction with sodium borohydride.[916] Aryl iodides add to alkynes using a platinum complex in conjunction with a palladium catalyst.[917] A palladium catalyst has been used alone for the same purpose,[918] and the intramolecular addition of a arene to an alkene was accomplished with a palladium[919] or a $GaCl_3$ catalyst,[920] Alkyl iodides add intramolecularly to alkenes with a titanium catalyst,[921] or to alkynes using indium metal and additives.[922] The latter cyclization of aryl iodides to alkenes was accomplished with indium and iodine[923] or with SmI_2.[924]

Aromatic hydrocarbons, such as benzene add to alkenes using a ruthenium catalyst[925] a catalytic mixture of $AuCl_3/AgSbF_6$,[926] or a rhodium catalyst,[927] and ruthenium complexes catalyze the addition of heteroaromatic compounds, such as pyridine, to alkynes.[928] Such alkylation reactions are clearly reminiscent of the Friedel–Crafts reaction (**11-11**). Palladium catalysts can also be used to for the addition of aromatic compounds to alkynes,[929] and rhodium catalysts for addition to alkenes (with microwave irradiation).[930] Note that vinylidene cyclopropanes react with furans and a palladium catalyst to give allylically substituted furans.[931]

Arylboronic acids (p. 905) add to alkynes to give the substituted alkene using a rhodium catalyst.[932] Allenes react with phenylboronic acid and an aryl iodide, in the presence of a palladium catalyst, to give a substituted alkene.[933] 2-Bromo-1,6-dienes react with phenylboronic acid with a palladium catalyst to give a cyclopentane with an exocyclic double bond and a benzyl substituent.[934]

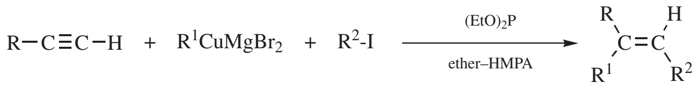
Organomanganese reagents add to alkenes.[935] Manganese triacetate [$Mn(OAc)_3$], in the presence of cupric acetate, facilitates intramolecular cyclization of a halide unit to an alkene.[936] A combination of $Mn(OAc)_2$ and $Co(OAc)_2$ catalysts, and an oxygen atmosphere in acetic acid, leads to addition of ketones to simple alkenes, give the 2-alkyl ketone.[937] Alkynes react with indium reagents, such as $(allyl)_3In_2I_3$, to form dienes (allyl substituted alkenes from the alkyne).[938] Allylic halides add to propargyl alcohols using indium metal to form the aryl organometallic *in situ*.[939] Allyltin reagents add to alkynes in a similar manner in the presence of $ZrCl_4$.[940] Alkylzinc reagents add to alkynes to give substituted alkenes in the presence of a palladium catalyst.[941] Allylzinc reagents add to alkynes in the presence of a cobalt catalyst.[942] A variation reacts dialkylzinc compounds with a 7-oxabicyclo[2.2.1]hept-2-ene system to give incorporation of the alkyl group and opening of the ring to give a cyclohexenol derivative.[943] Vinyltellurium add to alkynes in the presence of $CuI/PdCl_2$.[944]

An indirect addition converts alkynes to an organozinc compound using a palladium catalyst, which then reacts with allylic halides.[945] Similarly, the reaction of an alkyne with $Ti(OiPr)_4$/2 *i*PrMgCl followed by addition of an alkyne leads to a conjugated diene.[946]

OS 81, 121.

15-22 The Addition of Two Alkyl Groups to an Alkyne

Dialkyl-addition



Two different alkyl groups can be added to a terminal alkyne[947] in one laboratory step by treatment with an alkylcopper-magnesium bromide reagent (called *Normant*

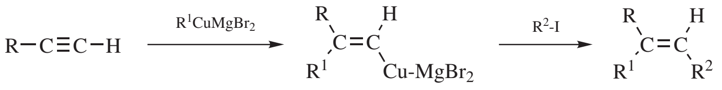
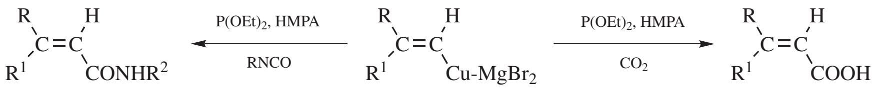
reagents)[948] and an alkyl iodide in ether–HMPA containing triethyl phosphite.[949] The groups add stereoselectively syn. The reaction, which has been applied to primary[950] R′ and to primary, allylic, benzylic, vinylic, and α-alkoxyalkyl R′, involves initial addition of the alkylcopper reagent,[951] followed by a coupling reaction (**10-57**):



136

Acetylene itself (R =H) undergoes the reaction with R_2CuLi instead of the Normant reagent.[952] The use of R′ containing functional groups has been reported.[953] If the alkyl iodide is omitted, the vinylic copper intermediate



136 can be converted to a carboxylic acid by the addition of CO_2 (see **16-30**) or to an amide by the addition of an isocyanate, in either case in the presence of HMPA and a catalytic amount of triethyl phosphite.[954] The use of I_2 results in a vinylic iodide.[955]

Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes (R_3Al), with zirconium complexes as catalysts.[956] Allyl ethers and iodobenzene have also been added using a

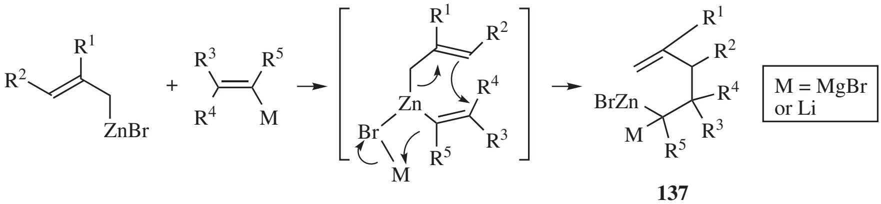
zirconium complex.[957] Similarly, allyl ethers and allyl chlorides have been added.[958]



137

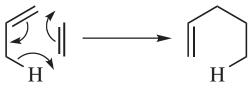
Allylic zinc bromides add to vinylic Grignard and lithium reagents to give the gem-dimetallo compounds **137**. The two metallo groups can be separately reacted with various nucleophiles.[959]

Arylboronic acids (p. 905) react with alkynes and 1 equivalent of an aryl iodide, with a palladium catalyst, to add two aryl groups across the triple bond.[960]

OS **VII**, 236, 245, 290.

15-23 The Ene Reaction

Hydro-allyl-addition



Alkenes can add to double bonds in a reaction different from those discussed in **15-20**, which, however, is still formally the addition of RH to a double bond. This is called the *ene reaction* or the *ene synthesis.*[961] For the reaction to proceed without a catalyst, one of the components must be a reactive dienophile (see **15-60** for a definition of this word), such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene such as propene. Rather high reaction temperatures (250–450°C) are common unless the substrates are very

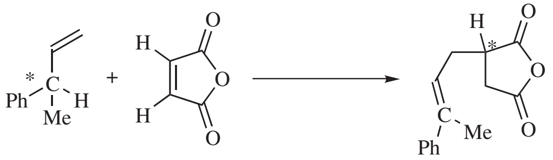
activated. Note that steric acceleration of the uncatalyzed ene reaction is known.[962] Cyclopropene has also been used.[963] The reaction is compatible with a variety of functional groups that can be appended to the ene and dienophile.[964] *N,N*-Diallyl amides give an ene cyclization, for example.[965] The ene reaction is known with fullerene (see p. 94) derivatives.[966] There has been much discussion of the mechanism of this reaction, and both concerted pericyclic (as shown above) and stepwise



138

mechanisms have been suggested. The mechanism of the ene reaction of singlet ($^1\Delta_g$) oxygen with simple alkenes was found to involve two steps, with no intermediate.[967] A retro-ene reaction is known with allylic dithiocarbonate.[968] The reaction between maleic anhydride and optically active $PhCHMeCH{=}CH_2$ gave an optically active product (**138**),[969] which is strong evidence for a concerted rather than a stepwise mechanism.[970] The reaction can be highly stereoselective.[971]

The reaction can be extended to less-reactive enophiles by the use of Lewis acid catalysts, especially alkylaluminum halides.[972] Titanium catalysts,[973] $Sc(OTf)_3$,[974]

$LiClO_4$[975] yttrium,[976] nickel catalysts,[977] as well as a combination of silver and gold catalysts[978] have also been used. A magnesium-ene cyclization stereochemically directed by an allylic oxyanionic group has been reported.[979] The Lewis acid catalyzed reaction probably has a stepwise mechanism.[980] The ene reaction has also been mediated on certain resins,[981] and using formaldehyde that was encapsulated in zeolite.[982] An iridium catalyzed ene reaction has been done in an ionic liquid.[983] The carbonyl-ene reaction is also very useful, and often gives synthetically useful yields of products when catalyzed by Lewis acids,[984] including asymmetric catalysts.[985] Among the useful Lewis acids are scandium triflate[986] and chromium complexes.[987] Carbonyl ene cyclization has been reported on silica gel at high pressure (15 kbar).[988] Ene reactions with imines,[989] nitrile oxides,[990] as well as nitroso ene reactions are known.[991]

This is called the *Michael reaction* and involves conjugate addition.[992] The compound RCH_2Z or RCHZZ′ can include aldehydes,[993] ketones,[994] esters[995] and diesters,[996] diketones,[997] keto-esters,[998] carboxylic acids and dicarboxylic acids,[999] nitriles,[1000] and nitro compounds,[1001] often with chiral catalysts or additives that give asymmetric induction. Enamines can also be used as the nucleophilic partner in Michael additions.[1002] In the most common examples, a base removes the acidic proton and then the mechanism is as outlined on p. 1008. The reaction has been carried out with conjugated substrates that include malonates, cyanoacetates, acetoacetates, other β-keto esters, and compounds of the form ZCH_3, ZCH_2R, $ZCHR_2$, and ZCHRZ′, including carboxylic esters, amides,[1003] ketones, aldehydes, nitriles, nitro compounds,[1004]

and sulfones, as well as other compounds with relatively acidic hydrogens, such as indenes and fluorenes. Vinylogous Michael reaction are well known, using a variety of nucleophilic species.[1005] Michael addition of methyl 2,2-dichloroacetate/ $LiN(TMS)_2$ where TMS = trinethysilyl, leads to formation of a cyclopropane ring.[1006] Similarly, the intramolecular Michael addition of an α-chloro ketone enolate anion, formed *in situ* using DABCO, leads to formation of a bicyclo[4.1.0] diketone.[1007] It is noted that activated aryl compounds undergo Michael addition in the presence of an imidazolidinone catalyst.[1008] Conjugate addition of nitrones using SmI_2 has been reported.[1009]

These reagents do not add to ordinary double bonds, except in the presence of free-radical initiators (**15-33**). 1,2 Addition (to the C=O or C≡N group) often competes and sometimes predominates (**16-38**).[1010] In particular, α,β-unsaturated *aldehydes* seldom give 1,4 addition.[1011] The Michael reaction has traditionally been performed in protic solvents, with catalytic amounts of base,[1012] but more recently better yields with fewer side reactions have been obtained in some cases by using an equimolar amount of base to convert the nucleophile to its enolate form (*preformed enolate*). In particular, preformed enolates are often used where stereoselective reactions are desired.[1013] Silyl enol ethers can also be used, and in conjunction with chiral additives.[1014] Phase-transfer catalysts have been used,[1015] and ionic liquids have been used in conjunction with phase-transfer catalysis.[1016] Michael addition has been done in ionic liquids, adding aldehydes to conjugated nitro compounds using proline as a catalyst.[1017] Transition-metal compounds, such as $CeCl_3$,[1018] $Yb(OTf)_3$,[1019] $Bi(OTf)_3$,[1020] ferric chloride hexahydrate,[1021]

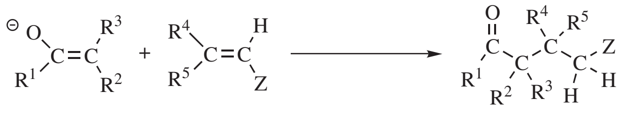
copper compounds,[1022] lanthanum complexes,[1023] ruthenium complexes,[1024] or scandium complexes[1025] also induce the reaction. In many cases, such compounds lead to catalytic enantioselective Michael additions.[1026] Conjugate addition has also been promoted by Y-zeolite,[1027] and water-promoted Michael additions have also been reported.[1028] Other catalysts have also been used.[1029] Vinylzinc complexes add to conjguated keotnes in the presence of a CuBr catlayst.[1030]

In a Michael reaction with suitably different R groups, two new stereogenic centers are created (see **139**).



139

In a diastereoselective process, one of the two pairs is formed exclusively or predominantly, as a racemic mixture.[1031] Many such examples have been reported.[672] In many of these cases, both the enolate anion and substrate can exist as (*Z*) or (*E*) isomers. With enolates derived from ketones or carboxylic esters, The (*E*) enolates gave the syn pair of enantiomers (p. 166), while (*Z*) enolates gave the anti pair.[1032] Nitro compounds add to conjugated ketones in the presence of a dipeptide and a piperazine.[1033] Malonate derivatives also add to conjugated ketones,[1034] and keto esters add to conjugated esters.[1035] Addition of chiral additives to the reaction, such as metal–salen complexes,[1036] proline derivatives,[1037] or (−)-sparteine,[1038]

lead to product formation with good-to-excellent asymmetric induction. Ultrasound has also been used to promote asymmetric Michael reactions.[1039] Intramolecular versions of Michael addition are known.[1040] A double Michael process is possible, where conjugate addition to an alkynyl ketone is followed by an intramolecular Michael to form a functionalized ring.[1041]

When either or both of the reaction components has a chiral substituent, the reaction can be enantioselective (only one of the four diastereomers formed predominantly).[1042] Enantioselective addition has also been achieved by the use of a chiral catalyst[1043] and by using optically active enamines instead of enolates.[1044] Chiral imines have also been used.[1045]

Mannich bases (see **16-19**) and β-halo carbonyl compounds can also be used as substrates; these are converted to the C=C–Z compounds *in situ* by the base (**16-19**, **17-13**).[1046] Substrates of this kind are especially useful in cases where the C=C–Z compound is unstable. The reaction of C=C–Z compounds with enamines (**10-69**) can also be considered a Michael reaction. Michael reactions are reversible.

When the substrate contains *gem*-Z groups (e.g., **141**), bulky groups can be added, if the reaction is carried out under aprotic conditions. For example, addition of enolate **140** to **141** gave **142** in which two adjacent quaternary centers have been formed.[1047]

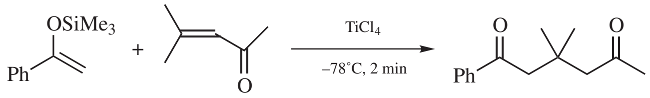
In certain cases, Michael reactions can take place under acidic conditions.[1048] Michael-type addition of radicals to conjugated carbonyl compounds is also known.[1049] Radical addition can be catalyzed by $Yb(OTf)_3$,[1050] but radicals add under standard conditions as well, even intramolecularly.[1051] Electrochemical-initiated Michael additions are known.

Michael reactions are sometimes applied to substrates of the type C≡C—Z, where the coproducts are conjugated systems of the type C=C—Z.[1052] Indeed, because of the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for nonactivated alkynes (e.g., acetylene), to be substrates in this reaction.[1053]

In a closely related reaction, silyl enol ethers add to α,β-unsaturated ketones and esters when catalyzed[1054] by $TiCl_4$, for example,[1055]



$InCl_3$ also catalyzes this reaction.[1056] Aluminum compounds also catalyze this reaction[1057] and the reaction has been done in neat tri-*n*-propylaluminum.[1058] A solid-state version of the reaction used alumina•$ZnCl_2$.[1059] This reaction, also, has been performed diastereoselectively.[1060] Tin enolates have been used.[1061]

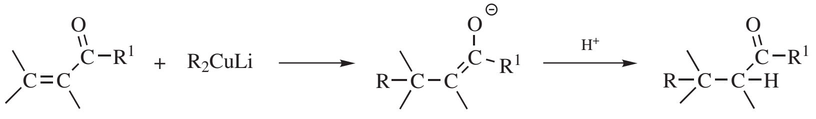
15-25 1,4 Addition of Organometallic Compounds to Activated Double Bonds

Hydro-alkyl-addition



143

Lithium dialkylcopper reagents (see **10-57**) add to α,β-unsaturated aldehydes[1062] and ketones (R′ =H, R, Ar) to give conjugate addition products[1063] in a reaction closely related to the Michael reaction. α,β-Unsaturated esters are less reactive,[1064] and the corresponding acids do not react at all. R can be primary alkyl, vinylic,[1065] or aryl. If Me_3SiCl is present, the reaction takes place much faster and with higher yields; in this case the product is the silyl enol ether of **143** (see **12-17**).[1066] The use of Me_3SiCl also permits good yields with allylic R groups.[1067] Conjugated alkynyl-ketones also react via 1,4-addition to give substituted alkenyl-ketones.[1068]

Various functional groups, such as OH and unconjugated C=O groups, may be present in the substrate.[1069] Conjugated sulfones are also good substrates.[1070] An excess of the cuprate reagent relative to the conjugated substrate is often required. In general, only one of the R groups of R_2CuLi adds to the substrate; the other is wasted. This can be a limitation where the precursor (RLi or RCu, see **12-36**) is expensive or available in limited amounts, particularly if an excess of the reagent

[1070]Domínguez, E.; Carretero, J.C. *Tetrahedron Lett.* ***1993***, *34*, 5803.

is required. The difficulty of group transfer can be overcome by using one of the mixed reagents $R(R'C{\equiv}C)CuLi$,[1071] $R(O{-}t{-}Bu)CuLi$,[1072] $R(PhS)CuLi$,[1073] each of which transfers only the R group. Mixed reagents are easily prepared by the reaction of RLi with $R'C{\equiv}CCu$ ($R' = n$-Pr or t-Bu), t-BuOCu, or PhSCu, respectively. A further advantage of the mixed reagents is that good yields of addition product are achieved when R is tertiary, so that use of one of them permits the introduction of a tertiary alkyl group. The mixed reagents R(CN)CuLi[1074] (prepared from RLi and CuCN) and $R_2Cu(CN)Li_2$[1075] also selectively transfer the R group.[1076] Other mixed reagents incorporate a ligand that is not easily transferred, such as $R(R'Se)Cu(CN)Li_2$, leading to selective transfer of the R group.[1077] The reaction has also been carried out[1078] with α,β-acetylenic ketones,[1079] esters, and nitriles.

Both Grignard and R_2CuLi reagents[1080] have also been added to systems of the form $C{\equiv}C{-}C{=}O$.[1081] Conjugate addition to α,β-unsaturated and acetylenic acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents $RCu{\bullet}BF_3$ (R = primary).[1082] Alkylcopper compounds RCu (R = primary or secondary alkyl) have also been used with tetramethylethylenediamine and Me_3SiCl to give silyl enol ethers from α,β-unsaturated ketones in high yield.[1083] Amine units have been transferred in this manner using α-lithio amides, CuCN, and additives ranging from LiCl to $Me_2NCH_2SnBu_3$, which gave conjugate addition of an amidomethyl unit, $-CH_2N(Me)Boc$.[1084] Other amino-cuprates are known to give conjugate addition reactions.[1085]

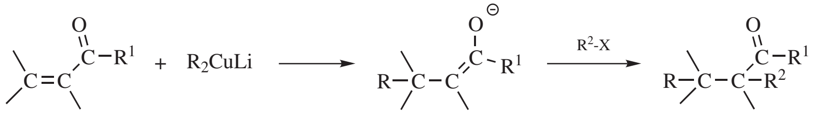
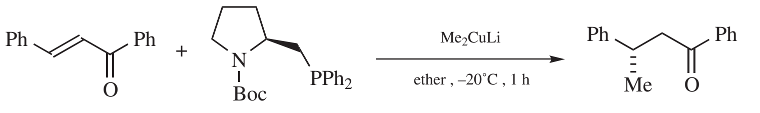
There is generally little or no competition from 1,2-addition (to the C=O). However, when R is allylic, 1,4-addition is observed with some substrates and 1,2-addition with others.[1086] R_2CuLi also add to α,β-unsaturated sulfones[1087] but not to simple α,β-unsaturated nitriles.[1088] Organocopper reagents (RCu), as well as certain R_2CuLi add to α,β-unsaturated and acetylenic sulfoxides.[1089]



143

Conjugate addition of the cuprate to the α,β-unsaturated ketone leads to an enolate ion, **143**. It is possible to have this enolate anion reacts with an electrophilic species (*tandem vicinal difunctionalization*), in some cases at the O and in other cases at the C.[1090] For example, if an alkyl halide R^2X is present (R^2 = primary alkyl or allylic), the enolate **143** can be alkylated directly.[1091] Thus, by this method, both the α and β positions of a ketone are alkylated in one synthetic operation (see also, **15-22**).



144

As with the Michael reaction (**15-24**) the 1,4-addition of organometallic compounds has been performed diastereoselectively[1092] and enantioselectively.[1093]

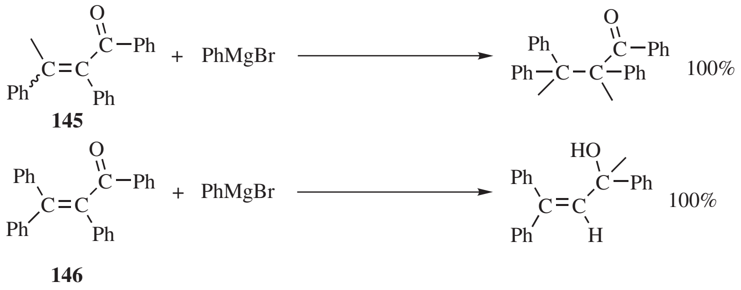
The influence of solvent and additives on yield and selectivity has been examined.[1094] The conjugate addition of dimethyl cuprate in the presence of a chiral ligand, such as **144**, is an example.[1095] The use of chiral ligands with MgI_2/I_2 and Bu_3SnI gave conjugate addition products with α,β-unsaturated amides with good % ee.[1096] Chiral bis(oxazoline) copper catalysts have been used for the conjugate addition of indoles to α,β-unsaturated esters.[1097] Chiral templates have also been used with Grignard reagents, directly[1098] and in the presence of $AlMe_2Cl$.[1099] Many of the examples cited below involve the use of chiral additives, chiral catalysts, or chiral templates.



Grignard reagents also add to conjugated substrates such as α,β-unsaturated ketones, cyano-ketones,[1100] esters, and nitriles,[1101] but 1,2-addition may seriously compete:[1102] The product is often controlled by steric factors. Thus **145** with phenylmagnesium bromide gives 100% 1,4-addition, while **146** gives 100% 1,2-addition. In general, substitution at the carbonyl group increases 1,4-addition, while substitution at the double bond increases 1,2-addition. In most cases, both products are obtained, but α,β-unsaturated *aldehydes* nearly always give exclusive 1,2-addition when treated with Grignard reagents. However, the extent of 1,4-addition of Grignard reagents can be increased by the use of a copper ion catalyst, for example, CuCl, $Cu(OAc)_2$.[1103] A dialkyl copper–magnesium iodide complex (R_2Cu•MgI) has been used for conjugate addition to chiral α,β-unsaturated amides.[1104] Grignard reagents mixed with $CeCl_3$ generates a reactive species that gives primarily 1,4-addition.[1105] It is likely that alkylcopper reagents, formed from RMgX and

Cu^+ (cupric acetate is reduced to cuprous ion by excess RMgX), are the actual attacking species in these cases.[1063] Alkylidene malonic ester derivatives, $C{=}C(CO_2R)$, increase the facility of 1,4-addition with the two electron withdrawing groups.[1106] Alkylidene amido esters, $C{=}C(CO_2R)NHCOAr$, react with $EtI/Mg(ClO_4)_2$ and Bu_3SnH, in the presence of BEt_3/O_2 and a chiral ligand, to give the ethylated product $EtCHCH(CO_2R)NHCOAr$.[1107] This is probably a radical process (see **15-35**).

Organolithium reagents[1108] generally react with conjugated aldehydes, ketones and esters by 1,2-addition,[1109] but 1,4-addition was achieved with esters of the form C=C–COOAr, where Ar was a bulky group such as 2,6-di-*tert*-butyl-4-methoxyphenyl.[1110] Alkyllithium reagents can be made to give 1,4-addition with α,β-unsaturated ketones[1111] and aldehydes[1112] if the reactions are conducted in the presence of HMPA.[1113] Among organolithium reagents that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see **10-71**),[1114] vinyllithium reagents,[1115] and α-lithio allylic amides.[1116] Lithium–halogen exchange (**12-22**) generates an organolithium species that adds intramolecularly to conjugated esters to give cyclic and bicyclic products.[1117] 1,4-Addition of alkyllithium reagents to α,β-unsaturated aldehydes can also be achieved by converting the aldehyde to a benzothiazole derivative (masking the aldehyde function),[1118] from which the aldehyde group can be regenerated. When some conjugated acids are added to organolithium reagents, the conjugate addition product was isolated in good yield.[1119] α,β-Unsaturated nitro compounds undergo conjugate addition with aryllithium reagents, and subsequent treatment with acetic acid gives the α-aryl ketone.[1120]

If the organolithium reagent is modified, 1,4-addition is more successful. The reaction of an aryllithium reagent with $B(OMe)_3$, for example, led to a rhodium-catalyzed conjugate addition with excellent enantioselectivity in when a chiral ligand was employed.[1121] Allylic tellurium reagents that are treated with lithium diisopropyl amide, and then conjugated esters give the 1,4-addition product, which cyclizes to form the corresponding cyclopropane derivative.[1122]

Boron reagents add to conjugated carbonyl compounds.[1123] Alkynyl borate esters (p. 815) give conjugate addition in the presence of boron trifluoride etherate,[1124] as do arylboronic acids (p. 815) with a rhodium,[1125] palladium,[1126] or a bismuth catalyst.[1127] Diethylzinc has also been used.[1128] Aryl boronic acids add to the double bond of vinyl sulfones in the presence of a rhodium catalyst.[1129] Similarly, $LiBPh(OMe)_3$ and a rhodium catalyst gave conjugate addition of the phenyl group to α,β-unsaturated esters.[1130] Potassium vinyltrifluoroborates (see p. 607) give 1,4-addition with a rhodium catalyst,[1131] as do aryltrifluoroborates.[1132]

Organozinc compounds add to conjugated systems. The use of chiral ligands is effective for conjugate addition of dialkylzinc compounds to α,β-unsaturated ketones, esters, and so on,[1133] including conjugated lactones.[1134] Many dialkylzinc compounds can be used, including vinylzinc compounds.[1135] Dialkylzinc

compounds and a chiral complex leads to enantioselective conjugate addition in conjunction with $Cu(OTf)_2$[1136] or other copper compounds.[1137] Diethylzinc adds to conjugated nitro compounds in the presence of a catalytic amount of $Cu(OTf)_2$ to give the conjugate addition product.[1138] Other transition-metal compounds can be used in conjunction with dialkylzinc compounds[1139] or with arylzinc halides (ArZnCl).[1140] Reaction of alkyl iodides with Zn/CuI with ultrasound generates an organometallic that adds to conjugated esters.[1141] Diarylzinc compounds (prepared with the aid of ultrasound) in the presence of nickel acetylacetonate, undergo 1,4-addition not only to α,β-unsaturated ketones, but also to α,β-unsaturated aldehydes.[1142] Mixed alkylzinc compounds also add to conjugated systems.[1143] Functionalized allylic groups can be added to terminal alkynes with allylic halides, zinc, and ultrasound, to give 1,4-dienes.[1144] Internal alkynes undergo 1,4-addition to conjugated esters using a combination of zinc metal and a cobalt complex as catalysts.[1145]

Trialkylalanes R_3Al add 1,4 to α,β-unsaturated carbonyl compounds in the presence of nickel acetylacetonate[1146] or $Cu(OTf)_2$.[1147] In the presence of aluminum chloride, benzene reacts with conjugated amides to add a phenyl group to C-4.[1148] Alkyl halides react via conjugate addition using BEt_3 or $AlEt_3$.[1149] An alkynyl group can be added to the double bond of an α,β-unsaturated ketone by use of the diethylalkynylalane reagents $Et_2AlC{\equiv}CR$.[1150] In a similar manner, the alkenyl reagents $R_2AlCH{=}CR$ transfer an alkenyl group.[1151]

Terminal alkynes add to conjugated systems when using a ruthenium,[1152] palladium,[1153] or a rhodium catalyst.[1154] Triphenylbismuth (Ph_3Bi) and a rhodium catalyst gives conjugate addition of the phenyl group upon exposure to air.[1155] Similar reactivity is observed with a palladium catalyst in aqueous media.[1156] Lithium tetraalkylgallium reagents give 1,4-addition.[1157] Trimethyl(phenyl)tin and a rhodium catalyst gives conjugate addition of a methyl group[1158] and tetraphenyltin and a palladium catalyst adds a phenyl group.[1159] Allyltin compounds add an allyl group in the presence of a scandium catalyst.[1160] Benzylic bromides add to conjugated nitriles using a 2:1 mixture of $CrCl_3$ and manganese metal.[1161] Electrochemical conjugate addition to α,β-unsaturated ketones was reported using aryl halides and a cobalt catalyst.[1162] Aryl halides add in the presence of $NiBr_2$.[1163] Vinyl zirconium complexes undergo conjugate addition when using a rhodium catalyst.[1164] Pyrrole adds to conjugated alkynyl esters in the presence

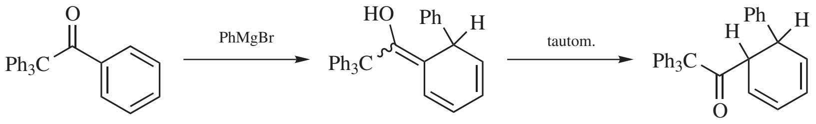
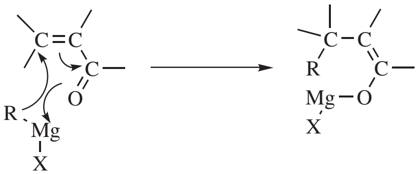
of palladium acetate, to give the 2-alkenyl pyrrole.[1165]



147

In certain cases, Grignard reagents add 1,4 to *aromatic* systems to give **147** after tautomerization (p. $$$) of the initial formed enol.[1166] Such cyclohexadienes are easily oxidizable to benzenes (often by atmospheric oxygen), so this reaction becomes a method of alkylating and arylating suitably substituted (usually hindered) aryl ketones. A similar reaction has been reported for aromatic nitro compounds where 1,3,5-trinitrobenzene reacts with excess methylmagnesium halide to give 2,4,6-trinitro-1,3,5-trimethylcyclohexane.[1167]



The mechanisms of most of these reactions are not well known. The 1,4 uncatalyzed Grignard reaction has been postulated to proceed by the cyclic mechanism shown, but there is evidence against it.[1168] The R_2CuLi[1169] and copper-catalyzed Grignard additions may involve a number of mechanisms, since the actual attacking species and substrates are so diverse.[1170] A free-radical mechanism of some type

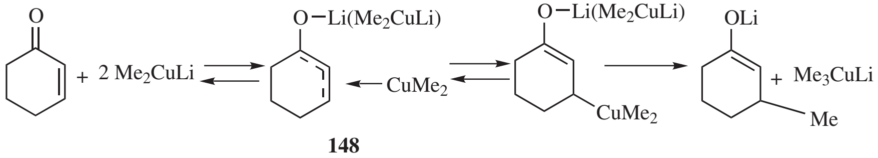
(perhaps SET) has been suggested[1171] although the fact that retention of configuration at R has been demonstrated in several cases rules out a completely free R• radical.[1172] For simple α,β-unsaturated ketones, such as 2-cyclohexenone, and Me_2CuLi, there is evidence[1173] for this mechanism:



148 is a *d*,π* complex, with bonding between copper, as a base supplying a pair of *d* electrons, and the enone as a Lewis acid using the π* orbital of the allylic system.[1173] The ^{13}C NMR spectrum of an intermediate similar to **148** has been reported.[1174]

For the addition of organocopper reagents to alkynes and conjugated dienes, see **15-22**.

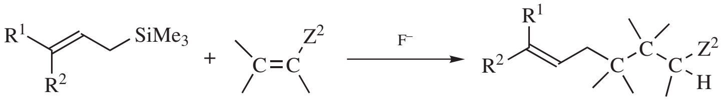
15-26 The Sakurai Reaction



Allylic silanes $R_2C{=}CHCH_2SiMe_3$ can be used instead of silyl enol ethers (the *Sakurai reaction*).[1175] An allyl group can be added, to α,β-unsaturated carboxylic esters, amides and nitriles, with $CH_2{=}CHCH_2SiMe_3$ and F^- ion (see **15-47**).[1176] This reagent gave better results than lithium diallylcuprate (**15-25**). Catalytic Sakurai reactions are known.[1177] The palladium catalyzed reaction of conjugated ketones with $PhSi(OEt)_3$ with $SbCl_3$ and Bu_4NF in acetic acid gave the 1,4-addition product.[1178] A similar reaction was reported using $PhSi(OMe)_3$

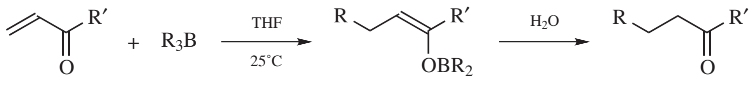
with a rhodium catalyst.[1179] In a related reaction, Ph_2SiCl_2, NaF and a rhodium catalyst gives conjugate addition of a phenyl group to α,β-unsaturated ketones.[1180] An interesting rhodium-catalyzed, conjugate addition of a phenyl group was reported using a siloxane polymer bearing Si—Ph units.[1181]

Silyl ketene acetals, RCH=C(OMe)$OSiMe_3$, add to conjugated ketones to give δ-keto esters, in $MeNO_2$ as solvent.[1182]

15-27 Conjugate Addition of Boranes to Activated Double Bonds

Hydro-alkyl-addition (overall transformation)



R′ = H, Me

Just as trialkylboranes add to simple alkenes (**15-16**), they rapidly add to the double bonds of acrolein, methyl vinyl ketone, and certain of their derivatives in THF at 25°C to give enol borinates (also see, p. 631), which can be hydrolyzed to aldehydes or ketones.[1183] If water is present in the reaction medium from the beginning, the reaction can be run in one laboratory step. Since the boranes can be prepared from alkenes (**15-16**), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group, such as crotonaldehyde (CH_3CH=CHCHO) and 3-penten-2-one, fail to react under these conditions, as does acrylonitrile, but these compounds can be induced to react by the slow and controlled addition of O_2 or by initiation with peroxides or UV light.[1184] A disadvantage is

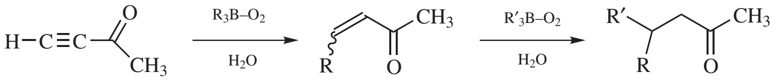
[1184]Brown, H.C.; Kabalka, G.W. *J. Am. Chem. Soc.* ***1970***, *92*, 712, 714. See also, Utimoto, K.; Tanaka, T.; Furubayashi, T.; Nozaki, H. *Tetrahedron Lett.* ***1973***, 787; Miyaura, N.; Kashiwagi, M.; Itoh, M.; Suzuki, A. *Chem. Lett.* ***1974***, 395.

that only one of the three R groups of R_3B adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a β-alkyl borinate, such as **149**,[1185] which can be prepared as shown. **149** (R = *tert*-butyl) can be made by treatment of **149** (R = OMe) with *t*-BuLi. The use of this reagent permits *tert*-butyl groups to be added. β-1-Alkenyl-9-BBN compounds β-RCH = CR′-9-BBN (prepared by treatment of alkynes with 9-BBN or of RCH=CR′Li with β-methoxy-9-BBN[1186]) add to methyl vinyl ketones to give, after hydrolysis, γ,δ-unsaturated ketones,[1187] although β-R-9-BBN, where R = a saturated group, are not useful here, because the R group of these reagents does not preferentially add to the substrate.[1184] The corresponding β-1-alkynyl-9-BBN compounds also give the reaction.[1188] Like the three substrates mentioned above, 3-butyn-2-one fails to react in the absence of air, but undergoes the reaction when exposed to a slow stream of air:[1189] Since the product, **150**, is an α,β-unsaturated ketone, it can be made to react with another BR_3, the same or different, to produce a wide variety of ketones **151**.



150 **151**

Vinyl boranes add to conjugated ketones in the presence of a rhodium catalyst (with high asymmetric induction in the presence of BINAP).[1190] Alkynyl-boranes also add to conjugated ketones, in the presence of BF_3.[1191]

The fact that these reactions are catalyzed by free-radical initiators and inhibited by galvinoxyl[1192] (a free-radical inhibitor) indicates that free-radical mechanisms are involved.

15-28 Radical Addition to Activated Double Bonds

Hydro-alkyl-addition

In a reaction similar to **15-25**, alkyl groups can be added to alkenes activated by, such groups as COR′, COOR′, CN, and even Ph.[1193] In the method illustrated above, the R group comes from an alkyl halide (R = primary, secondary, or tertiary alkyl; X = Br or I) and the hydrogen from the tin hydride. The reaction of *tert*-butyl bromide, Bu_3SnH and AIBN (p. 935), for example, adds a *tert*-butyl group to a conjugated ester via 1,4-addition.[1194] An alkene is converted to an alkylborane with catecholborane (p. 817) and when treated with a conjugated ketone and O_2, radical conjugate addtion leads to the β-substituted ketone.[1195] Organomercury hydrides (RHgH) generated *in situ* from RHgX and $NaBH_4$, can also be used.[1196] When the tin method is used, Bu_3SnH can also be generated in a similar way, from R_3SnX and $NaBH_4$. The tin method has a broader scope (e.g., it can be used on $CH_2{=}CCl_2$), but the mercury method uses milder reaction conditions. Like **15-27**, these additions have free-radical mechanisms. The reaction has been used for free-radical cyclizations of the type discussed on p. 1125.[1197] Such cyclizations normally give predominant formation of 15-membered rings, but large rings (11–20 members) have also been synthesized by this reaction.[1198]

Free-radical addition of an aryl group and a hydrogen has been achieved by treatment of activated alkenes with a diazonium salt and $TiCl_3$.[1199] The addition of R_3Al takes place by a free-radical mechanism.[1146]

OS **VII**, 105.

15-29 Radical Addition to Unactivated Double Bonds[1200]

Alkyl-hydro-addition

Radical addition to alkenes is usually difficult, except when addition occurs to conjugated carbonyl compounds (**15-24**). An important exception involves radicals bearing a heteroatom α to the carbon bearing the radical center. These radical are much more stable and can add to alkenes, usually with anti-Markovnikov orientation, as in the radical induced addition of HBr to alkenes (**15-2**).[1201] Examples of this type of reaction include the use of alcohol-, ester-,[1202] amino-, and aldehyde-stabilized radicals.[455] Carbon tetrachloride can be cleaved homolytically to generate Cl• and Cl_3C•, which can add to alkenes. The alkyl group of alkyl iodides adds to alkenes with BEt_3/O_2 as the initiator and in the presence of a tetraalkylammonium hypophosphite.[1203] When chloroform was treated with a ruthenium carbene complex, Cl_2CH add to the less substituted carbon of an alkene, and Cl to the more substituted carbon.[1204] The radical generated from $(EtO)_2POCH_2Br$ adds to alkenes to generate a new phosphonate ester.[1205] α-Bromo esters add to alkenes in the presence of BEt_3/air to give a γ-bromo ester.[1206] α-Bromo amides add the Br and the acyl carbon to an alkene using $Yb(OTf)_3$ with BEt_3/O_2 as the radical initiator.[1207] α-Iodo amides add to alkenes using a water soluble azobis initiator to give the iodo ester, which cyclizes under the reaction conditions to give a lactone.[1208] β-Keto dithiocarbonates, RC(=O)—C—SC(=S)OEt, generate the radical in the presence of a peroxide and add to alkenes.[1209] Malonate derivatives add to alkenes in the presence of a mixture of Mn/Co catalyst, in oxygenated acetic acid.[1210]

Other radicals can add to alkenes, and the rate constant for the addition of methyl radicals to alkenes has been studied,[1211] and the rate of radical additions to alkenes in general has also been studied.[1212] The kinetic and thermodynamic control of a radical addition regiochemistry has also been studied.[1213] Alkynes are generally less reactive than alkenes in radical coupling reactions.[1214] Nonradical nucleophiles usually react faster with alkynes than with alkenes, however.[1215]

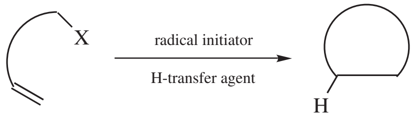
15-30 Radical Cyclization[1216]

Alkyl-hydro-addition



ω-Haloalkenes generate radicals upon treatment with reagents, such as AIBN or under photolysis conditions,[1217] and the radical carbon adds to the alkene to form cyclic compounds.[1218] This intramolecular addition of a radical to an alkene is called radical cyclization. In a typical example, haloalkene **154** reacts with the radical produced by AIBN to give radical **153**. The radical can add to the more substituted carbon to give **155** via a 5-exo–trig reaction (p. 305).[1219] If the radical adds to the less substituted carbon, **156** is formed via a 6-endo–trig reaction.[1220] In both cases, the product is another radical, which must be converted to an unreactive product. This is generally accomplished by adding a hydrogen transfer agent,[1221] such as tributyltin hydride (Bu_3SnH), which reacts with **155** to form methylcyclopentane and Bu_3Sn•, or with **156** to give cyclohexane. The Bu_3Sn• formed in both cases usually dimerizes to form $Bu_3SnSnBu_3$. Cyclization can compete with hydrogen transfer[1222] of Bu_3SnH to **153** to give **152**, the reduction product. In general, formation of the five-membered ring dominates the cyclization, but if addition to the C=C unit is relatively slow, the reduction product is formed preferentially. Radical rearrangements can also diminish the yield of the desired product.[1223] Given a choice between a larger and a smaller ring, radical cyclization generally gives the smaller ring,[1224] but not

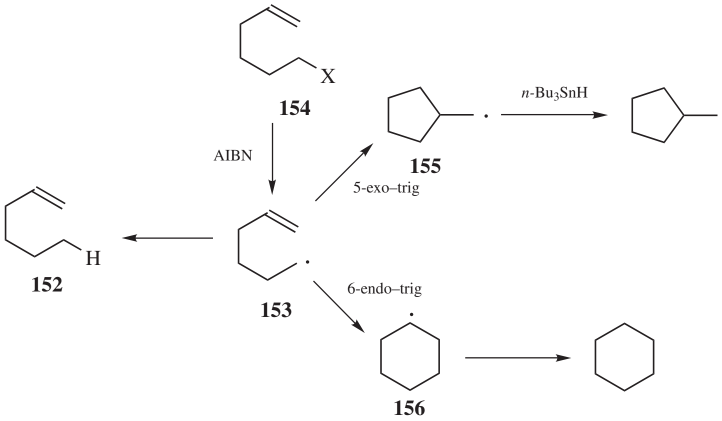
always.[1225] The mechanism of this reaction has been discussed.[1226] Formation of other size rings is possible of course. A 4-exo–trig radical cyclization has been studied,[1227] selectivity in a 7-endo versus 6-exo cyclization,[1228] and also an 8-endo-trig reaction.[1229] In radical cyclization to form large rings, 1,5- and 1,9-hydrogen atom abstractions can pose a problem[1230]



In cases where hydrogen atom transfer gives primarily reduced products, $Bu_3Sn{-}SnBu_3$ under photochemical generates the radical which can cyclize (see **15-46**),[1231] but a halogen atom transfer agent, such as iodoethane, is used rather than a hydrogen-transfer agent, so the final product is an alkyl iodide.

A mixture of a Grignard reagent and $CoCl_2$ has also been used to initiate aryl radical cyclizations.[1232] Titanium(III)-mediated radical cyclizations are known,[1233] and SmI_2-mediate reactions are possible in the presence of a nickel catalyst.[1234] Organoborane-mediated radical cyclizations are known.[1235] Electrochemically generated radicals also cyclize.[1236] The influence of the halogen atom on radical cyclization has been studied.[1237] Both phenylthio[1238] and phenylseleno

groups[1239] can be used as 'leaving groups' for radical cyclization, where sulfur or selenium atom transfer leads to formation of the radical. A seleno ester, R_2N—CH_2C(—O)SeMe, has also been used with $(Me_3Si)_3SiH$ (tristrimethylsilylsilane, TTMSS) and AIBN to generate R_2NCH_2•.[1240] *O*-Phosphonate esters have also served as the leaving group.[1241] *N*-(2-bromophenylbenzyl)methylamino groups have been used as leaving groups for formation of a radical.[1242] Alkenes also serve as radical precursors, adding to another alkene,[1243] including conjugated systems.[1244]

Radical cyclization reaction often proceeds with high diastereoselectivity[1245] and high asymmetric induction when chiral precursors are used. Internal alkynes are good substrates for radical cyclization,[1246] but terminal alkynes tend to give mixtures of *exo/endo–dig* products (p. 305).[1247] *N*-Alkenyl pyridinium salts, with ortho-halogen substituents generate the aryl radical with Bu_3SnH/AIBN, which cyclizes on the pendant alkene unit.[1248] Cyclization of vinyl radicals[1249] and allenyl radicals[1250] are also well known. Ring expansion during radical cyclization is possible when the terminal intermediate is a cyclobutylcarbinyl radical.[1251]

Aryl radicals participate in radical cyclization reactions when the aromatic ring has an alkene or alkyne substituent. *o*-Iodo aryl allyl ethers cyclize to benzofuran derivatives, for example, when treated with AIBN, aqueous H_3PO_2 and $NaHCO_3$ in ethanol.[1252] Cyclization of an *o*-bromo-*N*-acyl aniline (a methacrylic acid derivative) with AIBN/Bu_3SnH gave an indolone under the typical conditions used for cyclization of alkenes.[1253]

Radical cyclization is compatible with the presence of other functional groups. Treatment of $XCH_2CON(R)$—$C(R^1)$=CH_2 derivatives (X = Cl, Br, I) with Ph_3SnH

and AIBN led to formation of a lactam via radical cyclization.[1254] Cyclization of *N*-iodoethyl-5-vinyl-2-pyrrolidinone led to the corresponding bicyclic lactam,[1255] and there are other examples of radical cyclization with molecules containing a lactam unit[1256] or an amide unit.[1257] β-Lactams can be produced by radical cyclization, using $Mn(OAc)_3$.[1258] Radical cyclization occurs with enamines as well.[1259] Photochemical irradiation of *N,N*-diallyl acrylamide leads to formation of a lactam ring, and in this case thiophenol was added to generate the phenylthio derivative.[1260] Phenylseleno *N*-allylamines lead to cyclic amines.[1261] ω-Iodo acrylate esters cyclize to form lactones,[1262] and allylic acetoxy compounds of the type $C{=}C{-}C{-}O_2C{-}CH_2I$ cyclize in a similar manner to give lactones.[1263] Iodolactonization (p. 1154) occurs under standard radical cyclization conditions using allylic acetoxy compounds[1264] and $HGaCl_2/BEt_3$ has been used to initiate the radical process.[1265] α-Bromo mixed acetals give α-alkoxy tetrahydrofuran derivatives[1266] and α-iodoacetals cyclize to give similar products.[1267] The reaction of an ortho-alkynyl aryl isonitrile with AIBN and 2.2 equivalents of Bu_3SnH gave an indole via 5-exo–digcyclization.[1268] Indole derivatives have also been prepared from ortho-iodo aniline derivatives, using AIBN and tristrimethylsilylsilane (TTMSS).[1269]

Acyl radicals can be generated and they cyclize in the usual manner.[1270]A polyene-cyclization reaction generated four rings, initiating the sequence by treatment

of a phenylseleno ester with Bu_3SnH/AIBN to form the acyl radical, which added to the first alkene unit.[1271] The newly formed carbon radical added to the next alkene, and so on. Acyl radicals generated from Ts(R)NCOSePh derivatives cyclize to form lactams.[1272]

Radical cyclization of iodo aldehydes or ketones, at the carbon of the carbonyl, is effectively an acyl addition reaction (**16-24**, **16-25**). This cyclization is often reversible, and there are many fewer examples can addition to an alkene or alkyne. In one example, a δ-iodo aldehyde was treated with BEt_3/O_2 to initiate formation of the radical, and in the presence of Bu_3SnH cyclization gave a cyclopentanol.[1273] The reaction of an aldehyde-alkene with AIBN, 0.5 $PhSiH_3$ and 0.1 Bu_3SnH generated a radical from the alkene, which cyclized at the aldehyde to give cyclopentanol derivatives.[1274] An aldehyde-*O*-methyloxime generated a radical adjacent to nitrogen under standard conditions, which cyclized at the carbonyl to give a cyclic α-hydroxy *N*-methoxyamine.[1275] Alternatively an α-bromoacetal-*O*-methyl oxime cyclized at the C=NOMe unit under electrolytic conditions in the presence of cobaloxime.[1276]

The attacking radical in radical cyclization reactions is not limited to a carbon, and a number of heterocycles can be prepared.[1277] Amidyl radical are known and give cyclization reactions.[1278] Aminyl radical cyclizations have been reported.[1279] *N*-Chloroamine-alkenes give an aminyl radical when treated with $TiCl_3$•BF_3, and cyclization give a pyrrolidine derivative with a pendant chloromethyl group.[1280] *N*-(S-substituted) amines give similar results using AIBN/Bu_3SnH.[1281] Oxime–alkenes cyclize to imines when treated with PhSSPh and TEMPO (p. 274).[1282] An oxygen radical can be generated under photochemical conditions, and they add to alkenes in a normal manner.[1283] Note that radical substitution occurs, and reaction of Ph_3SnH/AIBN and an *O*-amidyl compound having a phosphonate ester elsewhere in the molecule gave cyclization to a tetrahydrofuran derivative.[1284]

15-31 Conjugate Addition With Heteroatom Nucleophiles

Other nucleophiles add to conjugated systems to give Michael-type products. Aniline derivatives add to conjugated aldehydes in the presence of a catalytic amount of DBU (p. 1132).[1285] Amines add to conjugated esters in the presence of $InCl_3$,[1286] $Bi(NO)_3$,[1287] $Cu(OTf)_2$,[1288] $CeCl_3/NaI/SiO_2$,[1289] $La(OTf)_3$,[1290] or $Yb(OTf)_3$ at 3 kbar,[1291] for example, to give β-amino esters. Palladium catalysts have been used as well.[1292] Conjugate addition of amines has also been promoted by lithium perchlorate,[1293] and by clay.[1294] This reaction can be initiated photochemically[1295] or with microwave irradiation.[1296] Lithium amides add to conjugated esters to give the β-amino ester.[1297] An intramolecular addition of an amine unit to a conjugated ketone in the presence of a palladium catalyst, or photochemically, led to cyclic amines.[1298] Amines add to conjugated thio-lactams.[1299] Chiral catalysts lead to enantioselective reactions.[1300] Chiral imines add in a highly stereoselective manner.[1301] Chiral additives, such as chiral Cinchona alkaloids[1302] or chiral naphthol derivatives,[1303] have also been used. The nitrogen of carbamates add to conjugated ketones with a platinum,[1304] palladium,[1305] copper,[1306] or with a bis-(triflamide) catalyst.[1307] The amine moiety of a carbamate adds to conjugated

ketones with a polymer-supported acid catalyst,[1308] or with BF_3•OEt_2.[1309] Chiral catalysts have been used for the conjugated addition of carbamates.[1310] The reaction of ammonium formate with 1,4-diphenylbut-2-en-1,4-dione, in PEG-200 and a palladium catalyst under microwave irradiation, gave 2,5-diphenylpyrrole.[1311]

Lactams have been shown to add to conjugated esters in the presence of $Si(OEt)_4$ and CsF.[1312] Phthalimide adds to alkylidene malononitriles via 1,4-addition with a palladium catalyst, and the resulting anion can be alkylated with an added allylic halide.[1313] Alkylidene amido amides, C=C(NHAc)CONHR, react with secondary amines in water to give the β-amino amido amide.[1314] Amines also add in a conjugate manner to alkynyl phosphonate esters, C≡C–$PO(OEt)_2$, using a CuI catalyst.[1315] Hydroxylamines add to conjugated nitro compounds to give 2-nitro hydroxylamines.[1316] *N,O*-Trimethylsilyl hydroxylamines add to conjugated esters, via nitrogen, using a copper catalyst.[1317] Trimethylsilyl azide with acetic acid reacts with conjugated ketones to give the β-azido ketone.[1318] Sodium azide adds to conjugated ketones in aqueous acetic acid and 20% PBu_3.[1319]

Phosphines react similarly to amines under certain conditions. Conjugate addition of R_2PH and a nickel catalyst give conjugate addition to α,β-unsaturated nitriles.[1320]

Alcohols add to conjugated ketones with a PMe_3 catalyst to give the β-alkoxy ketone.[1321] The conjugate addition of peroxide anions (HOO^- and ROO^-) to α,β-unsaturated carbonyl compounds is discussed in **15-48**.

bis(Silanes) add to alkylidene malonate derivatives in the presence of a copper catalyst to give β-silyl malonates, $RCH(SiR_3)CH(CO_2Me)_2$.[1322] Alkylsilane units add using bis(trialkylsilyl)zinc reagents with a CuCN catalyst.[1323]

Thiophenol and butyllithium (lithium phenylthiolate) adds to conjugated esters.[1324] Similar addition is observed with selenium compounds RSeLi.[1325]

Thiols react with conjugated amides via 1,4-addition with the addition of 10% $Hf(OTf)_4$ or other lanthanide triflates[1326] or to conjugated ketones in ionic solvents.[1327] Thiophenol adds in a similar manner in the presence of Na_2Ca-P_2O_7[1328] or LiAl–poly2a.[1329] Thioaryl moieties can be added in the presence of Yb[1330] or a catalytic amount of $(DHQD)_2PYR$ (a dihydroquinidine, see **15-48**).[1331] Thioalkyl units, such as BuS—, add to conjugated ketones using BuS—SnBu and In—I.[1332] Addition of conjugated lactones is possible to produce β-arylthiolated lactones.[1333]

α,β-Unsaturated sulfones undergo conjugate addition of a cyano group using Et_2AlCN.[1334] Trimethylsilyl cyanide (Me_3SiCN) adds a cyano group to α,β-unsaturated amines with a specialized aluminum salen-ytterbium catalyst.[1335]

15-32 Acylation of Activated Double Bonds and of Triple Bonds

Hydro-acyl-addition

Under some conditions, acid derivatives add directly to activated double bonds. Acetic anhydride, magnesium metal, and Me_3SiCl reacts with conjugated esters to give a γ-keto ester.[1336] Similar reaction with vinyl phosphonate esters leads to a γ-keto phosphonate ester.[1337] Thioesters undergo conjugate addition to α,β-unsaturated ketones in the presence of SmI_2.[1338] Using DBU (1,8-diazabicyclo [5.4.0] undec-7-ene) (p. 1132) and a thioimidazolium salt, acyl silanes, $Ar(C{=}O)SiMe_3$, add in a similar manner.[1339] Under microwave irradiation, aldehydes add to conjugated ketones using DBU/Al_2O_3 and a thiazolium salt.[1340] The conjugate addition

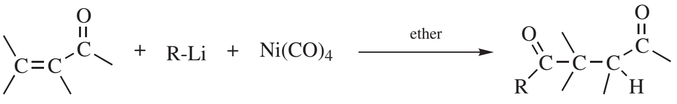
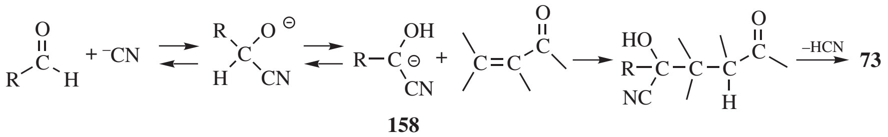
of acyl zirconium complexes in the presence of BF3•OEt_2 is catalyzed by palladium acetate.[1341]



157

An acyl group can be introduced into the 4 position of an α,β-unsaturated ketone by treatment with an organolithium compound and nickel carbonyl.[1342] The product is a 1,4-diketone, **157**. The R group may be aryl or primary alkyl. The reaction can also be applied to alkynes (which need not be activated), in which case 2 mol add and the product is also a 1,4-diketone (e.g., $R'C{\equiv}CH \rightarrow RCOCHR'CH_2COR$).[1343] In a different procedure, α,β-unsaturated ketones and aldehydes are acylated by treatment at −110°C with $R_2(CN)CuLi_2$ and CO. This method is successful for R = primary, secondary, and tertiary alkyl.[1344] For secondary and tertiary groups, R(CN)CuLi (which does not waste an R group) can be used instead.[1345]

Another method involves treatment with an aldehyde and cyanide ion (see **16-52**) in a polar aprotic solvent (e.g., DMF or DMSO).[1346]



This method has been applied to α,β-unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones, γ-keto esters, and γ-keto nitriles, respectively (see also, **16-55**). The ion **158** is a synthon for the unavailable $R^{\ominus}$ C=O anion (see also, p. 634); it is a masked $R^{\ominus}$ C=O anion. Other masked carbanions that have been used in this reaction are the $RC^{\ominus}$(CN) NR ion,[1347] the $EtSC^{\ominus}$ RSOEt ion[1348] (see p. 634), the $CH_2{=}C^{\ominus}$ OEt ion,[1349] $CH_2{=}C(OEt)Cu_2Li$,[1350] $CH_2{=}CMe(SiMe_3)$,[750]

and the RC$^{\ominus}$(OCHMeOEt) CN ion[1351] (see p. 640). In the last case, best results are obtained when R is a vinylic group. Anions of 1,3-dithianes (**10-71**) do not give 1,4-addition to these substrates (except in the presence of HMPA, see **15-25**), but add 1,2 to the C=O group instead (**16-38**).

In another procedure, acyl radicals derived from phenyl selenoesters ArCOSePh (by treatment of them with Bu_3SnH) add to α,β-unsaturated esters and nitriles to give γ-keto esters and γ-keto nitriles, respectively.[1352]

OS **VI**, 866; **VIII**, 620.

15-33 Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, and so on.

Hydro-acyl-addition, and so on.

Formates, primary, and secondary alcohols, amines, ethers, alkyl halides, compounds of the type Z—CH_2— Z′, and a few other compounds add to double bonds in the presence of free-radical initiators.[1353] This is formally the addition of RH to a double bond, but the "R" is not just any carbon but one connected to an oxygen or a nitrogen, a halogen, or to two Z groups (defined as on p. 1007). Formates and formamides[1354] add similarly:

W = OR, NH_2

Alcohols, ethers, amines, and alkyl halides add as follows (shown for alcohols):

ZCH_2Z' compounds react at the carbon bearing the active hydrogen:[1355]

Similar additions have been successfully carried out with carboxylic acids, anhydrides,[1356] acyl halides, carboxylic esters, nitriles, and other types of compounds.[1357]

Similar reactions have been carried out on acetylene.[1358] In an interesting variation, thiocarbonates add to alkynes in the presence of a palladium catalyst to give a β-phenylthio α,β-unsaturated ester.[1359] Aldehydes add to alkynes in the presence of a rhodium catalyst to give conjugated ketones.[1360] In a cyclic version of the addition of aldehydes, 4-pentenal was converted to cyclopentanone with a rhodium–complex catalyst.[1361] An intramolecular acyl addition to an alkyne was reported using silyl ketones, acetic aid and a rhodium catalyst.[1362] In the presence of a palladium catalyst, a tosylamide group added to an alkene unit to generate *N*-tosylpyrrolidine derivatives.[1363]

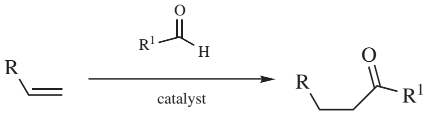
15-34 Addition of Aldehydes

Alkyl-carbonyl-addition



In the presence of metal catalysts, such as rhodium compounds[1364] or $Yb(OTf)_3$,[1365] aldehydes can add directly to alkenes to form ketones. The reaction of ω-alkenyl aldehydes with rhodium catalyst leads to cyclic ketones,[1366] with high enantioselectivity if chiral ligands are employed. Aldehydes also add to vinyl esters in the presence of hyponitrites and thioglycolates.[1367] The addition of aldehydes to activated double bonds, mediated by a catalytic amount of thiazolium salt in the presence of a

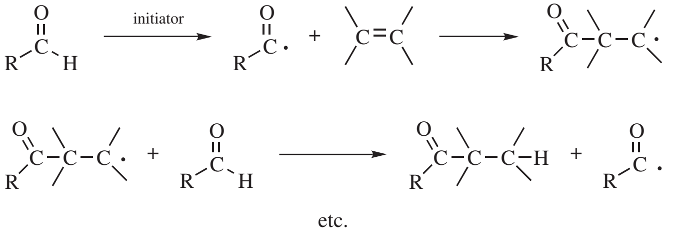
weak base, is called the *Stetter reaction*,[1368] An internal addition of an alkynyl aldehyde, catalyzed by a rhodium complex, led to a cyclopentenone derivative.[1369] A similar carbonyl addition with benzaldehyde derivatives having an ortho-allylic ether led to a benzopyranone when treated with potassium hexamethyldisilazide.[1370]

These reactions are not successful when the alkene contains electron-withdrawing groups, such as halo or carbonyl groups. A free-radical initiator is required,[1371] usually peroxides or *UV* light. The mechanism is illustrated for aldehydes but is similar for the other compounds:



Polymers are often side products. Photochemical addition of aldehyde to conjugated C=C units can be efficient when a triplet sensitizer (p. 340), such as benzophenone is used.[1372]

A variation that is more of an acyl addition (**16-25**) involves the reaction of an allylic alcohol with benzaldehyde. With a ruthenium catalyst and in an ionic liquid, the C=C unit reacts with the aldehyde, with concomitant oxidation of the allylic alcohol unit, to give a β-hydroxy ketone, PhCHO +C=C–CH(OH)R → PhCH(OH)–CH(Me)COR.[1373] In another variation, formate esters add to alkenes using a ruthenium catalyst to give an alkyl ester via a formylation process.[1374]

The acid-catalyzed hydrocarboxylation of alkenes (the *Koch reaction*) can be performed in a number of ways.[1375] In one method, the alkene is treated with carbon monoxide and water at 100–350°C and 500–1000-atm pressure with a mineral acid catalyst. However, the reaction can also be performed under milder conditions. If the alkene is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0–50°C and 1–100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.[1376] The formic acid procedure is called the *Koch–Haaf reaction* (the Koch–Haaf reaction can also be applied to alcohols, see **10-77**). Nearly all alkenes can be hydrocarboxylated by one or more of these procedures. However, conjugated dienes are polymerized instead. Hydrocarboxylation can also be accomplished under mild conditions (160°C and 50 atm) by the use of nickel carbonyl as catalyst. Acid catalysts are used along with the nickel carbonyl, but basic catalysts can also be employed.[1377] Other metallic salts and complexes can be used, sometimes with variations in the reaction procedure, including palladium,[1378] platinum,[1379] and rhodium[1380] catalysts. The $Ni(CO)_4$-catalyzed oxidative carbonylation with CO and water as a nucleophile is often called *Reppe carbonylation*.[1381] The toxic nature of nickel

tetracarbonyl has led to development of other catalysts, including Co, Rh, Ir, Pd, and Pt, and Mo compounds.[1382] This reaction converts alkenes, alkynes and dienes and is tolerant of a wide variety of functional groups. When the additive is alcohol or acid, saturated or unsaturated acids, esters, or anhydrides are produced (see **15-36**). The transition-metal-catalyzed carbonylation has been done enantioselectively, with moderate-to-high optical yields, by the use of an optically active palladium complex catalyst.[1383] Dienes react with Cp_2TiCl_2/RMgCl and then with Me_2NCOCl to give amides.[1384] In the presence of formic acid, CO, and palladium acids can similarly be formed.[1385] Alkenes also react with $Fe(CO)_5$ and CO to give carboxylic acids.[1386] Electrochemical carboxylation procedures have been developed, including the conversion of alkenes to 1,4-butanedicarboxylic acids.[1387]

When applied to triple bonds, hydrocarboxylation gives α,β-unsaturated acids under very mild conditions. Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with carbon dioxide and an electrically reduced nickel complex catalyst.[1388] Alkynes also react with $NaHFe(CO)_4$, followed by $CuCl_2$•2 H_2O, to give alkenyl acid derivatives.[1389] A related reaction with CO and palladium catalysts in the presence of $SnCl_2$ also leads to conjugated acid derivatives.[1390] Terminal alkynes react with CO_2 and $Ni(cod)_2$, and subsequent treatment with DBU (p. 1132) gives the α,β-unsaturated carboxylic acid.[1391]

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism[1392] involves initial attack by a proton, followed by attack of the resulting carbocation on carbon monoxide to give an acyl cation, which, with water, gives the product, **159**. Markovnikov's rule is followed, and carbon skeleton rearrangements and double-bond isomerizations (prior to attack by CO) are frequent.

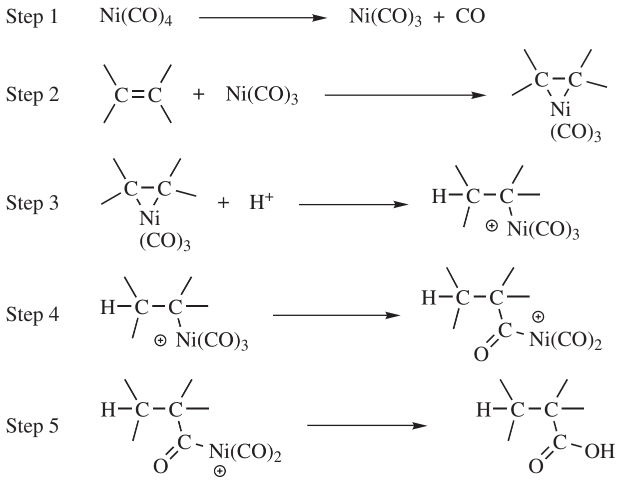
For the transition metal catalyzed reactions, the nickel carbonyl reaction has been well studied and the addition is syn for both alkenes and alkynes.[1393] The following is the accepted mechanism:[785]

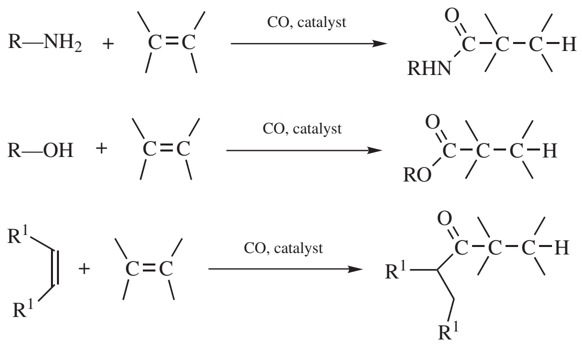


Step 3 is an electrophilic substitution. The principal step of the mechanism, step 4, is a rearrangement.

An indirect method for hydrocarboxylation involves the reaction of an alkene with a borate, $(RO)_2BH$ and a rhodium catalysts. Subsequent reaction with $LiCHCl_2$ and then $NaClO_2$ gives the Markovnikov carboxylic acid (RC=C → $RC(COOH)CH_3$.[1394] When a chiral ligand is used, the reaction proceeds with good enantioselectivity.

15-36 Carbonylation, Alkoxycarbonylation and Aminocarbonylation of Double and Triple Bonds

Alkyl, Alkoxy or Amino-carbonyl-addition



[1393]Bird, C.W.; Cookson, R.C.; Hudec, J.; Williams, R.O. *J. Chem. Soc.* ***1963***, 410.
[1394]Chen, A.; Ren, L.; Crudden, C.M. *J. Org. Chem.* ***1999***, *64*, 9704.

In the presence of certain metal catalysts, alkenes and alkynes can be carbonylated or converted to amides or esters.[1395] There are several variations. The reaction of an alkyl iodide and a conjugated ester with CO, $(Me_3Si)_3SiH$ and AIBN (p. 935) in supercritical CO_2 (p. 414) gave a γ-keto ester.[1396] Terminal alkynes react with CO and methanol, and in the presence of $CuCl_2$ and $PdCl_2$ the product is a β-chloro-α-β-unsaturated methyl ester.[1397] Conjugated dienes react with thiophenol, CO and palladium(II) acetate to give the β,γ-unsaturated thioester.[1398] Allene reacts with CO, methanol and a ruthenium catalyst go give methacrylic acid.[1399] 5-Iodo-1-pentene reacted with 40 atm of CO in butanol to give a cyclopentanone with a pendant ester ($—CH_2CO_2Bu$).[1400] Alkynes react with thiophenol and CO with a palladium[1401] or platinum[1402] catalyst to give a conjugated thioester. Terminal alkynes react with CO and methanol, using a combination of a palladium (II) halide and a copper (II) halide, to give a conjugated diester, $MeO_2C—C{=}C—CO_2Me$.[1403] A similar reaction with alkenes using a combination of a palladium and a molybdenum catalyst led to a saturated diester, $MeO_2C—C—C—CO_2Me$.[1404] Alkenes were converted to the dimethyl ester of 1,4-butanedioic acid derivatives with CO/O_2 and a combination of $PdCl_2$ and CuCl catalysts.[1405] Note that alkenes are converted to primarily the anti-Markovnikov ester upon treatment with arylmethyl formate esters ($ArCH_2OCHO$) and a ruthenium catalyst.[1406]

A bicyclic ketone was generated when 1,2-diphenylethyne was heated with CO, methanol and a dirhodium catalyst.[1407] 2-Iodostyrene reacted at 100°C with CO and a palladium catalyst to give the bicyclic ketone 1-indanone.[1408] Another variation reacted a conjugated allene–alkene with 5 atm of CO and a rhodium catalyst to give a bicyclic ketone.[1409] An intermolecular version of this reaction is known

using a cobalt catalyst, giving a cyclopentenone[1410] in a reaction related to the Pauson–Khand reaction (see below). The reaction of a conjugated diene having a distal alkene unit and CO with a rhodium catalyst led to a bicyclic conjugated ketone.[1411] When a Stille coupling (**12-15**) is done in a CO atmosphere, conjugated ketones of the type C=C—CO—C=C are formed,[1412] suitable for a Nazarov cyclization (**15-20**). Alkynes were converted to cyclobutenones using $Fe_3(CO)_{12}$ to form the initial complex, followed by reaction with copper(II) chloride.[1413] An interesting variation treated cyclohexene with 5 equivalents of Oxone® and a $RuCl_3$ catalyst to give 2-hydroxycyclohexanone.[1414]

The reaction of dienes, diynes, or en-ynes with transition metals[1415] (usually cobalt)[1416] forms organometallic coordination complexes. In the presence of carbon monoxide, the metal complexes derived primarily from enynes (alkene–alkynes) form cyclopentenone derivatives in what is known as the *Pauson–Khand reaction*.[1417] The reaction involves (*1*) formation of a hexacarbonyldicobalt–alkyne complex and (*2*) decomposition of the complex in the presence of an alkene.[1418] A typical example is formation of **160**.[1419] Cyclopentenones can be prepared by an intermolecular reaction of a vinyl silane and an alkyne using CO and a ruthenium catalyst.[1420] Carbonylation of an alkene–diene using a rhodium catalyst leads to cyclization to an α-vinyl cyclopentanone.[1421] An yne–diene can also be used for the Pauson–Khand reaction.[1422]

Rhodium,[1423] titanium,[1424] and tungsten[1425] complexes have also been used for this reaction. The reaction can be promoted photochemically[1426] and the rate is enhanced by the presence of primary amines.[1427] Coordinating ligands also accelerate the reaction,[1428] polymer-supported promoters have been developed[1429] and there are many possible variations in reaction conditions.[1430] The Pauson–Khand reaction has been done under heterogeneous reaction conditions,[1431] and with cobalt nanoparticles.[1432] A dendritic cobalt catalyst has been used.[1433] Ultrasound promoted[1434] and microwave promoted[1435] reactions have been developed. Polycyclic compounds (tricyclic and higher) are prepared in a relatively straightforward manner using this reaction.[1436] Asymmetric Pauson–Khand reactions are known.[1437]

The Pauson–Khand reaction is compatible with other groups or heteroatoms elsewhere in the molecule. These include ethers and aryl halides,[1438] esters,[1439]

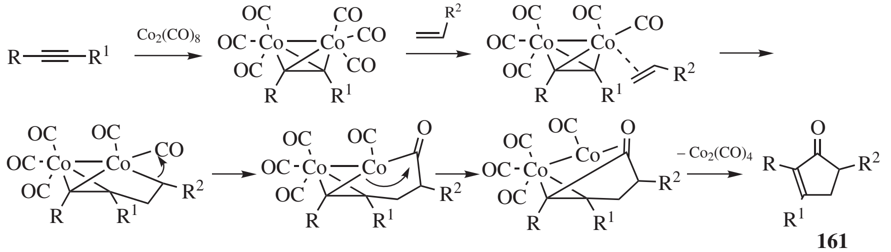
amides,[1440] alcohols,[1441] diols,[1442] and an indole unit.[1443] A silicon-tethered Pauson–Khand reaction is known.[1444] Allenes are reaction partners in the Pauson–Khand reaction.[1445] This type of reaction can be extended to form six-membered rings using a ruthenium catalyst.[1446] A double-Pauson–Khand process was reported.[1447] In some cases, an aldehyde can serve as the source of the carbonyl for carbonylation.[1448]

The accepted mechanism was proposed by Magnus,[1449] shown for the formation of **161**,[1450] and supported by Krafft's work.[1451] It has been shown that CO is lost from the Pauson–Khand complex prior to alkene coordination and insertion.[1452] Calculations concluded that the LUMO of the coordinated alkene plays a crucial role in alkene reactivity by determining the degree of back-donation in the complex.[1453]



161

Other carbonylation methods are available. Carbonylation occurs with conjugated ketones to give 1.4-diketones, using phenylboronic acid (**13-12**), CO and a rhodium catalyst.[1454] A non-carbonylation route treated a conjugated diene with an

excess of *tert*-butyllithium and quenching with carbon dioxide led to a cyclopentadienone.[1455] When quenched with CO rather than CO_2, a nonconjugated cyclopentenone was formed.[1456] It is noted that a carbonylation reaction with CO, a diyne and an iridium catalyst[1457] or a cobalt catalyst[1458] provided similar molecules.

The reaction of a secondary amine, CO, a terminal alkyne and *t*-$BuMe_2SiH$ with a rhodium catalyst led to a conjugated amide bearing the silyl group of the C=C unit.[1459] Reaction of a molecule containing an amine and an alkene unit was carboxylated with CO in the presence of a palladium catalyst to give a lactam.[1460] A similar reaction with a molecule containing an amine and an alkyne also generated a lactam, in the presence of CO and a rhodium catalyst.[1461] An intramolecular carbonylation reaction of a conjugated imine, with CO, ethylene and a ruthenium catalyst, led to a highly substituted β,γ-unsaturated lactam.[1462]

With any method, if the alkene contains a functional group, such as OH, NH_2, or $CONH_2$, the corresponding lactone (**16-63**),[1463] lactam (**16-74**), or cyclic imide may be the product.[1464] Titanium,[1465] palladium,[1466] ruthenium,[1467] and rhodium[1468] catalysts have been used to generate lactones. Allenic alcohols are converted to butenolides with 10 atm of CO and a ruthenium catalyst.[1469] Larger ring conjugated lactones can also be formed by this route using the appropriate allenic alcohol.[1470] Propargylic alcohols lead to β-lactones.[1471] Allenic tosyl-amides are converted to *N*-tosyl α,β-unsaturated pyrrolidinones using 20 atm of CO and a ruthenium catalyst.[1472] Conjugated imines are converted to similar products with CO, ethylene and a ruthenium catalyst.[1473] Propargyl alcohols are converted to

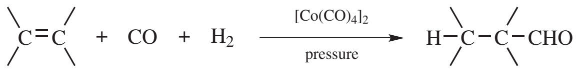
butenolides with CO/H_2O and a rhodium catalyst.[1474] Propargyl alcohols generate lactones when treated with a chromium pentacarbonyl carbene complex.[1475] Amines add to allenes, in the presence of CO and a palladium catalyst, to form conjugated amides.[1476]

15-37 Hydroformylation

Hydro-formyl-addition



Alkenes can be hydroformylated[1477] by treatment with carbon monoxide and hydrogen over a catalyst. The most common catalysts are cobalt carbonyls (see below for a description of the mechanism) and rhodium complexes,[1478] but other transition metal compounds have also been used. Cobalt catalysts are less active than the rhodium type, and catalysts of other metals are generally less active.[1479] Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal alkenes > straight-chain internal alkenes > branched-chain alkenes. With terminal alkenes, for example, the aldehyde unit is formed on both the primary and secondary carbon, but proper choice of catalyst and additive leads to selectivity for the secondary product[1480] or primary

product.[1481] Good yields for hydroformylation have been reported using rhodium catalysts in the presence of certain other additives.[1482] Among the side reactions are the aldol reaction (**16-34**), acetal formation, the Tishchenko reaction (**19-82**), and polymerization. In one case using a rhodium catalyst, 2-octene gave nonanal, presumably via a η^3-allyl complex (p. 116).[1483] Conjugated dienes give dialdehydes when rhodium catalysts are used[1484] but saturated mono-aldehydes (the second double bond is reduced) with cobalt carbonyls. Both 1,4- and 1,5-dienes may give cyclic ketones.[1485] Hydroformylation of triple bonds proceeds very slowly, and few examples have been reported.[1486] However, in the presence of a rhodium catalyst, the triple bond of a conjugated enyne is formylated.[1487] Many functional groups such as OH, CHO, COOR,[1488] CN, can be present in the molecule, although halogens usually interfere. Stereoselective syn addition has been reported,[1489] and also stereoselective anti addition.[1490] Asymmetric hydroformylation has been accomplished with a chiral catalyst,[1491] and in the presence of chiral additives.[1492] Cyclization to prolinal derivatives has been reported with allylic amines.[1493]

When dicobalt octacarbonyl, $[Co(CO)_4]_2$, is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt, $HCo(CO)_3$.[1494] Carbonylation $RCo(CO)_3 + CO \rightarrow RCo(CO)_4$ takes place, followed by a rearrangement and a

reduction of the C—Co bond, similar to steps 4 and 5 of the nickel carbonyl mechanism shown in **15-35**. The reducing agent in the reduction step is tetracarbonylhydrocobalt, $HCo(CO)_4$,[1495] or, under some conditions, H_2.[1496] When $HCo(CO)_4$ was the agent used to hydroformylate styrene, the observation of CIDNP indicated that the mechanism is different, and involves free radicals.[1497] Alcohols can be obtained by allowing the reduction to continue after all the carbon monoxide is used up. It has been shown[1498] that the formation of alcohols is a second step, occurring after the formation of aldehydes, and that $HCo(CO)_3$ is the reducing agent.

OS **VI**, 338.

15-38 Addition of HCN

Hydro-cyano-addition

Ordinary alkenes do not react with HCN, but polyhalo alkenes and alkenes of the form C=C—Z add HCN to give nitriles.[1499] The reaction is therefore a nucleophilic addition and is base catalyzed. When Z is COR or, more especially, CHO, 1,2-addition (**16-53**) is an important competing reaction and may be the only reaction. Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH_4Cl, and HCl or by Ni or Pd compounds.[1500] The HCN can be generated *in situ* from acetone cyanohydrin (see **16-52**), avoiding the use of the poisonous HCN.[1501] One or 2 equivalents of HCN can be added to a triple bond, since the initial product is a Michael-type substrate. Acrylonitrile is commercially prepared this way, by the addition of HCN to acetylene. Alkylaluminum cyanides, for example, Et_2AlCN, or mixtures of HCN and trialkylalanes R_3Al are especially good reagents for conjugate addition of HCN[1502] to α,β-unsaturated ketones and α,β-unsaturated acyl halides. Hydrogen cyanide can be added to ordinary alkenes in the presence of dicobalt octacarbonyl[1503] or certain other

transition-metal compounds.[1504] An indirect method for the addition of HCN to ordinary alkenes uses an isocyanide (RNC) and Schwartz's reagent (see **15-17**); this method gives anti-Markovnikov addition.[1505] *tert*-Butyl isocyanide and $TiCl_4$ have been used to add HCN to C=C—Z alkenes.[1506] Pretreatment with NaI/Me_3SiCl followed by CuCN converts alkynes to vinyl nitriles.[1507]

When an alkene is treated with Me_3SiCN and $AgClO_4$, followed by aq. $NaHCO_3$, the product is the isonitrile (RNC) formed with Markovnikov selectivity.[1508] An alternative reagent is the cyanohydrin of acetone, which adds to alkenes to give a nitrile in the presence of a nickel complex.[1509]

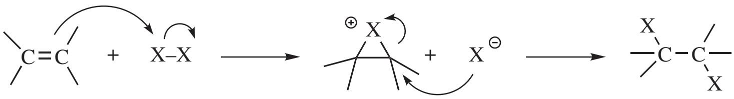
Most double bonds are easily halogenated[1510] with bromine, chlorine, or inter-halogen compounds.[1511] Substitution can compete with addition in some cases.[1512] Iodination has also been accomplished, but the reaction is slower.[1513] Under free-radical conditions, iodination proceeds more easily.[1514] However, *vic*-diiodides are generally unstable and tend to revert to iodine and the alkene.



162

The mechanism is usually electrophilic (see p. 1002), involving formation of an halonium ion (**162**),[1515] followed by nucleophilic opening to give the *vic*-dihalide. Nucleophilic attack is occurs with selectivity for the less substituted carbon with unsymmetrical alkenes. When free-radical initiators (or UV light) are present, addition can occur by a free-radical mechanism.[1516] Once Br• or Cl• radicals are formed, however, substitution may compete (**14-1** and **14-3**). This is especially important when the alkene has allylic hydrogens. Under free-radical conditions (UV light) bromine or chlorine adds to the benzene ring to give, respectively, hexabromo- and hexachlorocyclohexane. These are mixtures of stereoisomers (see p. 187).[1517]

Under ordinary conditions fluorine itself is too reactive to give simple addition; it attacks other bonds and mixtures are obtained.[1518] However, F_2 has been successfully added to certain double bonds in an inert solvent at low temperatures (−78°C), usually by diluting the F_2 gas with Ar or N_2.[1519] Addition of fluorine has also been accomplished with other reagents (e.g., *p*-Tol—IF_2/Et_3N•5 HF),[1520] and a mixture of PbO_2 and SF_4.[1521]

The reaction with bromine is very rapid and is easily carried out at room temperature,[1522] although the reaction is reversible under some conditions.[1523] In the case of bromine, an alkene•Br_2 complex has been detected in at least one case.[1524] Bromine is often used as a test, qualitative or quantitative, for unsaturation.[1525] The vast majority of double bonds can be successfully brominated. Even when aldehyde, ketone, amine, and so on functions are present in the molecule, they do not interfere, since the reaction with double bonds is faster. Bromination has been carried out in an ionic liquid.[1526]

Several other reagents add Cl_2 to double bonds, among them Me_3SiCl^- MnO_2,[1527] $NaClO_2/Mn(acac)_2$/moist Al_2O_3,[1528] $BnNEt_3MnO_4/Me_3SiCl$,[1529] and $KMnO_4$-oxalyl chloride.[1530] A convenient reagent for the addition of Br_2 to a double bond on a small scale is the commercially available pyridinium bromide perbromide $C_5H_5NH^+Br_3^-$.[1531] Potassium bromide with ceric ammonium nitrate, in water/dichloromethane, gives the dibromide.[1532] A combination of KBr and Selectfluor also give the dibromide.[1533] A combination of $CuBr_2$ in aq. THF and a chiral ligand led to the dibromide with good enantioselectivity.[1534] A mixture of (decyl)Me_3 $NMnO_4$ and Me_3SiBr is also an effective reagent.[1535] Either Br_2 or Cl_2 can also be added with $CuBr_2$ or $CuCl_2$ in the presence of a compound, such as acetonitrile, methanol, or triphenylphosphine.[1536]

Mixed halogenations have also been achieved, and the order of activity for some of the reagents is BrCl > ICl[1537] > Br_2 > IBr > I_2.[1538] Mixtures of Br_2 and Cl_2 have been used to give bromochlorination,[1539] as has tetrabutylammonium dichlorobromate, Bu_4NBrCl_2;[1540] iodochlorination has been achieved with $KICl_2$,[1541] $CuCl_2$, and either I_2, HI, or CdI_2; iodofluorination[1542] with mixtures of AgF and I_2;[1543] and mixtures of *N*-bromo amides in anhydrous HF give bromofluorination.[1544] Bromo-, iodo-, and chlorofluorination have also been achieved by treatment of the substrate with a solution of Br_2, I_2, or an *N*-halo amide in polyhydrogen fluoride-pyridine;[1545] while addition of I along with Br, Cl, or F has been accomplished with the reagent bis(pyridine)iodo(I) tetrafluoroborate $I(Py)_2BF_4$ and Br^-, Cl^-, or F^-, respectively.[1546] This reaction (which is also successful for triple bonds[1547]) can be extended to addition of I and other nucleophiles (e.g., NCO, OH, OAc, and NO_2).[1547] Cyclohexene is converted to *trans*-2-fluoroiodocyclohexane under electrolytic conditions using Et_4NI—Et_3N•HF in the reaction medium.[1548]

Conjugated systems give both 1,2- and 1,4-addition.[1518] Triple bonds add bromine, although generally more slowly than double bonds (see p. 1015). Molecules that contain both double and triple bonds are preferentially attacked at the double bond. Addition of 2 equivalents of bromine to triple bonds gives tetrabromo products. There is evidence that the addition of the first mole of bromine to a triple bond may take place by a nucleophilic mechanism.[1549] Molecular diiodine on Al_2O_3 adds to triple bonds to give good yields of 1,2-diiodoalkenes.[1550] Interestingly, 1,1-diiodo alkenes are prepared from an alkynyltin compound, via initial treatment with $Cp_2Zr(H)Cl$, and then 2.15 equivalents of iodine.[1551] A mixture of

$NaBO_3$ and NaBr adds two bromine atoms across a triple bond.[1552] With allenes it is easy to stop the reaction after only 1 equivalent has added, to give X—C—CX=C.[1553] Addition of halogen to ketenes gives α-halo acyl halides, but the yields are not good.

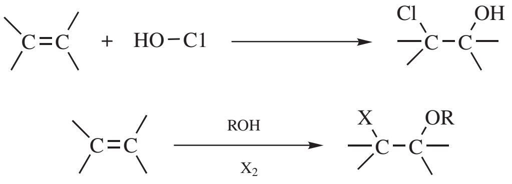
15-40 Addition of Hypohalous Acids and Hypohalites (Addition of Halogen, Oxygen)

Hydroxy-chloro-addition, and so on.[1554]
Alkoxy-chloro-addition, and so on.



Hypohalous acids (HOCl, HOBr, and HOI) can be added to alkenes[1555] to produce halohydrins.[1556] Both HOBr and HOCl are often generated *in situ* by the reaction between water and Br_2 or Cl_2, respectively. HOI, generated from I_2 and H_2O, also adds to double bonds, if the reaction is carried out in tetramethylene sulfone-$CHCl_3$[1557] or if an oxidizing agent, such as HIO_3 is present.[1558] Iodine and cerium sulfate in aqueous acetonitrile generates iodohydrins,[1559] as does iodine and ammonium acetate in acetic acid,[1560] or $NaIO_4$ with sodium bisulfite.[1561] The HOBr can also be conveniently added by the use of a reagent consisting of an *N*-bromo amide

(e.g., NBS or *N*-bromoacetamide) and a small amount of water in a solvent, such as DMSO or dioxane.[1562] *N*-Iodosuccinimide (NIS) in aqueous dimethoxyethane leads to the iodohydrin.[1563] An especially powerful reagent for HOCl addition is *tert*-butyl hydroperoxide (or di-*tert*-butyl peroxide) along with $TiCl_4$. This reaction is generally complete within 15 min at −78°C.[1564] Chlorohydrins can be conveniently prepared by treatment of the alkene with Chloramine T ($TsNCl^-$ Na^+)[1565] in acetone–water.[1566] The compound HOI can be added by treatment of alkenes with periodic acid and $NaHSO_3$.[1567] The reaction of an alkene with polymeric $(SnO)_n$, and then HCl with $Me_3SiOOSiMe_3$ leads to the chlorohydrin.[1568] Hypervalent iodine compounds react with an alkene and iodine in aqueous media to give the iodohydrin.[1569]

The compound HOF has also been added, but this reagent is difficult to prepare in a pure state and *explosions have occurred.*[1570]

The mechanism of HOX addition is electrophilic, with initial attack by the positive halogen end of the HOX dipole. Following Markovnikov's rule, the positive halogen goes to the side of the double bond that has more hydrogens (forming a more stable carbocation). This carbocation (or bromonium or iodonium ion in the absence of an aqueous solvent) reacts with ^-OH or H_2O to give the product. If the substrate is treated with Br_2 or Cl_2 (or another source of positive halogen such as NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain, directly $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OR$ or $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OCOR$, respectively (see also, **15-48**).[1571] Even the weak nucleophile $CF_3SO_2O^-$ can participate in the second step: The addition of Cl_2 or Br_2 to alkenes in the presence of this ion resulted in the formation of some β-haloalkyl triflates.[1572] There is evidence that the mechanism with Cl_2 and H_2O is different from that with HOCl.[1573] HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds —CX_2—CO—.

Alcohols and halogens react with alkenes to form halo ethers. When a homoallylic alcohol is treated with bromine, cyclization occurs to give a 3-bromotetrahydrofuran derivative.[1574] *tert*-Butyl hypochlorite (Me_3COCl), hypobromite, and hypoiodite[1575] add to double bonds to give halogenated *tert*-butyl ethers, X—C—C—$OCMe_3$. This is a convenient method for the preparation of tertiary ethers. Iodine and ethanol convert some alkenes to iodo-ethers.[1576] Iodine, alcohol and a $Ce(OTf)_2$ catalyst also generates the iodo-ether.[1577] When Me_3COCl or Me_3COBr is added to alkenes in the presence of excess ROH, the ether produced is $X-\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}-OR$.[1578] Vinylic ethers give β-halo acetals.[1579] A mixture of Cl_2 and SO_3 at −78°C converts alkenes to 2-chloro chlorosulfates $ClCHRCHROSO_2Cl$, which are stable compounds.[1580] Chlorine acetate [solutions of which are prepared by treating Cl_2 with $Hg(OAc)_2$ in an appropriate solvent] adds to alkenes to give acetoxy chlorides.[1581] Acetoxy fluorides have been obtained by treatment of alkenes with CH_3COOF.[1582]

For a method of iodoacetyl addition, see **15-48**.

An oxidative variation of this reaction treats a vinyl chloride with NaOCl and acetic acid, generating an α-chloro ketone.[1583]

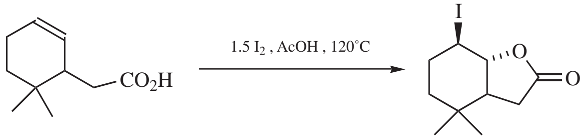
halolactonization.[1584]

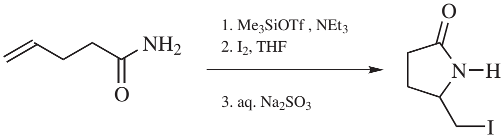


163 **164**

The most common version of this reaction is known as *iodolactonization*,[1585] and a typical example is the conversion of **163** to **164**.[1586] Bromo lactones and, to a lesser extent, chloro lactones have also been prepared. In general, addition of the halogen to an alkenyl acid, as shown, leads to the halo-lactone. Other reagents include $I^+(collidine)_2PF_6^-$,[1587] KI/sodium persulfate.[1588] Thallium reagents, along with the halogen, have also been used.[1589] When done in the presence of a chiral titanium reagent, I_2, and CuO, lactones are formed with good enantioselectivity.[1590] ICl has been used, with formation of a quaternary center at the oxygen-bearing carbon of the lactone.[1591]

In the case of γ,δ-unsaturated acids, 5-membered rings (γ-lactones) are predominantly formed (as shown above; note that Markovnikov's rule is followed), but 6-membered and even 4-membered lactones have also been made by this procedure. There is a gem-dimethyl effect that favors formation of 7–11-membered ring lactones by this procedure.[1592]

Formation of halo-lactams (**15-43**) by a similar procedure is difficult, but the problems have been overcome. Formation of a triflate followed by treatment with iodine leads to the iodo-lactam, **165**.[1593]



165

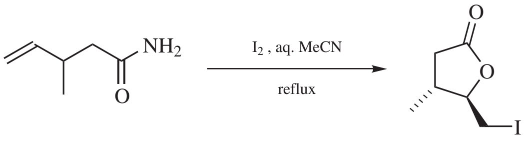
A related cyclization of *N*-sulfonyl-amino-alkenes and NBS gave the bromo-lactam,[1594] and a dichloro-*N,N*-bis(allylamide) was converted to a dichloro-lactam with $FeCl_2$.[1595] It is noted that lactone formation is possible from unsaturated amides. The reaction of 3-methyl *N,N*-dimethylpent-4-ene amide with iodine in aqueous acetonitrile, for example, gave iodolactone **166**.[1596]

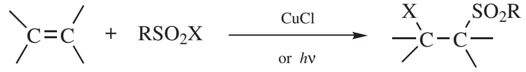


166

OS IX, 516.

15-42 Addition of Sulfur Compounds (Addition of Halogen, Sulfur)

Alkylsulfonyl-chloro-addition, and so on.[1597]



Sulfonyl halides add to double bonds, to give β-halo sulfones, in the presence of free-radical initiators or UV light. A particularly good catalyst is cuprous chloride.[1598] A combination of the anion $ArSO_2Na$, NaI, and ceric ammonium nitrate converts alkenes to vinyl sulfones.[1599] Triple bonds behave similarly, to give β-halo-α,β-unsaturated sulfones.[1600] In a similar reaction, sulfenyl chlorides, RSCl, give β-halo thioethers.[1601] The latter may be free-radical or electrophilic additions, depending on conditions. The addition of MeS and Cl has also been accomplished by treating the alkene with Me_3SiCl and Me_2SO.[1602] The use of Me_3SiBr and Me_2SO does not give this result; dibromides (**15-39**) are formed instead. β-Iodo

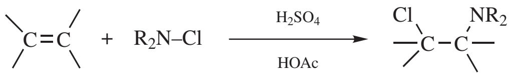
thiocyanates can be prepared from alkenes by treatment with I_2 and isothiocyanatotributylstannane Bu_3SnNCS.[1603] Bromothiocyanation can be accomplished with Br_2 and thallium(I) thiocyanate.[1604] Lead (II) thiocyanate reacts with terminal alkynes in the presence of $PhICl_2$ to give the bis(thiocyanato) alkene, ArC(SCN)—CHSCN.[1605] Such compounds were also prepared from alkenes using KSCN and $FeCl_3$.[1606] β-Halo disulfides, formed by addition of arenethiosulfenyl chlorides to double-bond compounds, are easily converted to thiiranes by treatment with sodium amide or sodium sulfide.[1607]

OS **VIII**, 212. See also OS **VII**, 251.

15-43 Addition of Halogen and an Amino Group (Addition of Halogen, Nitrogen)

Dialkylamino-chloro-addition



The groups R_2N and Cl can be added directly to alkenes, allenes, conjugated dienes, and alkynes, by treatment with dialkyl-*N*-chloroamines and acids.[1608] The reaction of $TsNCl_2$ and a $ZnCl_2$ catalyst gave the chloro tosylamine.[1609] These are free-radical additions, with initial attack by the $R_2NH^{\bullet +}$ radical ion.[1610] *N*-Halo amides RCONHX add RCONH and X to double bonds under the influence of uv light or chromous chloride.[1611] Amines add to allenes in the presence of a palladium catalyst.[1612] A mixture of *N*-(2-nosyl)NCl_2 and sodium *N*-(2-nosyl)NH^- with a CuOTf catalyst reacted with conjugated esters to give the *vicinal* (*E*)-3-chloro-2-amino ester.[1613] A variation of this latter reaction was done in an ionic liquid.[1614]

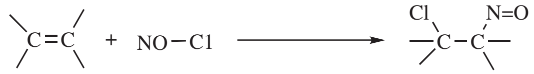
15-44 Addition of NOX and NO_2X (Addition of Halogen, Nitrogen)

Nitroso-chloro-addition



There are three possible products when NOCl is added to alkenes, a β-halo nitroso compound, an oxime, or a β-halo nitro compound.[1615] The initial product is always the β-halo nitroso compound,[1616] but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime, H—C–N=O → C=N–OH. With some alkenes, the initial β-halo nitroso compound is oxidized by the NOCl to a β-halo nitro compound.[1617] Many functional groups can be present without interference (e.g., COOH, COOR, CN, OR). The mechanism in most cases is probably simple electrophilic addition, and the addition is usually anti, although syn addition has been reported in some cases.[1618] Markovnikov's rule is followed, the positive NO going to the carbon that has more hydrogens.

Nitryl chloride NO_2Cl also adds to alkenes, to give β-halo nitro compounds, but this is a free-radical process. The NO_2 goes to the less-substituted carbon.[1619] Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro alkenes.[1620] The compound FNO_2 can be added to alkenes[1621] by treatment with HF in HNO_3[1622] or by addition of the alkene to a solution of nitronium tetrafluoroborate (NO_2^+ BF_4^-) (see **11-2**) in 70% polyhydrogen fluoride–pyridine solution[1623] (see also **15-37**).

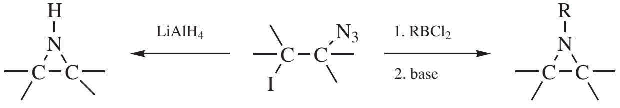
The addition of iodine azide to double bonds gives β-iodo azides.[1624] The reagent can be prepared *in situ* from KI—NaN_3 in the presence of Oxone®-wet alumina.[1625] The addition is stereospecific and anti, suggesting that the mechanism involves a cyclic iodonium ion intermediate.[1626] The reaction has been performed on many double-bond compounds, including allenes[1627] and α,β-unsaturated ketones. Similar reactions can be performed with BrN_3[1628] and ClN_3. 1,4-Addition has been found with acyclic conjugated dienes.[1629] In the case of BrN_3, both electrophilic and free-radical mechanisms are important,[1630] while with ClN_3 the additions are chiefly free radical.[1631] The compound IN_3 also adds to triple bonds to give β-iodo-α,β-unsaturated azides.[1632]



167 **168**

β-Iodo azides can be reduced to aziridines (**167**) with $LiAlH_4$[1633] or converted to *N*-alkyl- or *N*-arylaziridines (**168**) by treatment with an alkyl- or aryldichloroborane followed by a base.[1634] In both cases, the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (**10-31**) follows. With Chloramine T ($TsNCl^-$ Na^+) and 10% of pyridinium bromide perbromide, however, the reaction with alkenes give an *N*-tosyl aziridine directly.[1635]

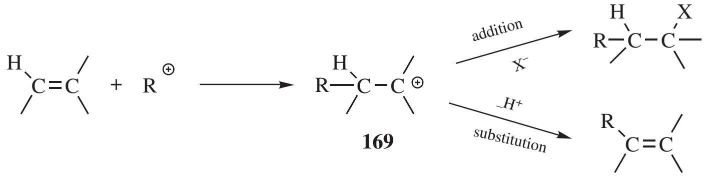
Alkyl halides can be added to alkenes in the presence of a Friedel–Crafts catalyst, most often $AlCl_3$.[1636] The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with **11-11**). Methyl and ethyl halides, which cannot rearrange to a more stable secondary or tertiary carbocation, give no reaction at all. The attacking species is the carbocation formed from the alkyl halide and the catalyst (see **11-11**).[1637] The addition therefore follows Markovnikov's rule, with the cation going to the carbon with more hydrogens. Substitution is a side reaction, arising from loss of hydrogen from the carbocation formed when an additional molecule of alkene attacks the initially formed carbocation (**169**). Conjugated dienes can add 1,4.[1638] Triple bonds also undergo the reaction, to give vinylic halides.[1639]



169

Simple polyhalo alkanes, such as CCl_4, $BrCCl_3$, ICF_3 and related molecules, add to alkenes in good yield.[1640] These are free-radical additions and require initiation, for example,[1641] by peroxides, metal halides (e.g., $FeCl_2$, CuCl),[1642] ruthenium catalysts,[1643] or UV light. The initial attack is by the carbon, and it goes to the carbon with more hydrogens, as in most free-radical attack:

$$RHC{=}CH_2 + \bullet CX_3 \longrightarrow R\dot{H}C{-}CH_2CX_3 \xrightarrow{CX_4} RH\overset{X}{\overset{|}{C}}{-}CH_2CX_3 + \bullet CX_3$$

This type of polyhalo alkane adds to halogenated alkenes in the presence of $AlCl_3$ by an electrophilic mechanism. This is called the *Prins reaction* (not to be confused with the other Prins reaction, **16-54**).[1644]

α-Iodolactones add to alkenes in the presence of BEt_3/O_2 to give the addition product.[1645] Other α-iodoesters add under similar conditions to give the lactone.[1646] Iodoesters also add to alkenes in the presence of BEt_3 to give iodo-esters that have not cyclized.[1647]

A variant of the free-radical addition method has been used for ring closure (see **15-30**).

For another method of adding R and I to a triple bond (see **15-23**).

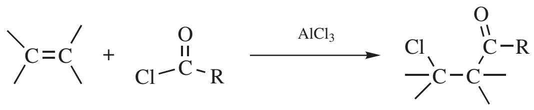
15-47 Addition of Acyl Halides (Addition of Halogen, Carbon)

Acyl-halo-addition



Acyl halides have been added to many alkenes, in the presence of Friedel–Crafts catalysts, although polymerization is a problem. The reaction has been applied to straight-chain, branched, and cyclic alkenes, but to very few containing functional groups, other than halogen.[1648] The mechanism is similar to that of **15-46**, and, as in that case, substitution competes (**12-16**). Increasing temperature favors substitution,[1649] and good yields of addition products can be achieved if the temperature is kept under 0°C. The reaction usually fails with conjugated dienes, since polymerization predominates.[1650] Iodo acetates have been formed from alkenes using iodine, $Pb(OAc)_2$ in acetic acid.[1651] The reaction can be performed on triple-bond compounds, producing compounds of the form RCO−C=C−Cl.[1652] A *formyl* group and a halogen can be added to triple bonds by treatment with *N,N*-disubstituted formamides

B. Oxygen, Nitrogen, or Sulfur on One or Both Sides

15-48 Hydroxylation (Addition of Oxygen, Oxygen)

Dihydroxy-addition

There are many reagents that add two OH groups to a double bond.[1655] The most common are OsO_4[1656] and alkaline $KMnO_4$,[1657] which give syn addition from the less-hindered side of the double bond. Less substituted double bonds are oxidized more rapidly than more substituted alkenes.[1658] Permanganate adds to alkenes to form an intermediate manganate ester (**171**), which is decomposed under alkaline conditions. Bases catalyze the decomposition of **171** by coordinating with the ester. Osmium tetroxide adds rather slowly but almost quantitatively to form a cyclic ester, such as **170**, as an intermediate, which can be isolated,[1659] but is usually decomposed solution, with sodium sulfite in ethanol or other reagents. The chief drawback to the use of OsO_4 is expensive and highly toxic, but the reaction is made catalytic in OsO_4 by using *N*-methylmorpholine-*N*-oxide (NMO),[1660] *tert*-butyl hydroperoxide in alkaline solution,[1661] H_2O_2,[1662] peroxyacid,[1663] flavin and

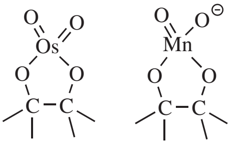
TEAA,[1664] $K_3Fe(CN)_6$[1665] and non-heme iron catalysts.[1666] Polymer-bound OsO_4,[1667] and encapsulated OsO_4 have been shown to give the diol in the presence of NMO,[1668] as well as OsO_4^{-2} on an ion exchange resin.[1669] Dihydroxylation has also been reported in ionic liquids,[1670] and with fluorous osmium tetroxide.[1671] A catalytic amount of K_2OsO_4 with a Cinchona alkaloid on a ordered inorganic support, in the presence of $K_3Fe(CN)_6$, gives the cis-diol.[1672] Oxidation of pent-4-en-1-ol to valerolactone was accomplished with Oxone® and a catalytic amount of OsO_4 in DMF.[1673]



170 **171**

The end-product of the reaction of either potassium permanganate or osmium tetroxide under the conditions described above is a 1,2-diol. Potassium permanganate is a strong oxidizing agent and can oxidize the glycol product[1674] (see **19-7** and **19-10**). In acid and neutral solution it always does so; hence glycols must be prepared with alkaline[1675] permanganate, but the conditions must be mild. Even so, yields are seldom >50%, although they can be improved with phase-transfer catalysis[1676] or increased stirring.[1677] The use of ultrasound with permanganate

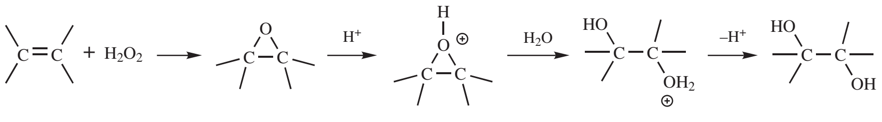
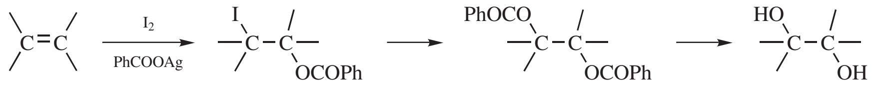
dihydroxylation has resulted in good yields of the diol.[1678] There is evidence that cyclic esters (**171**) are intermediates for OsO_4 dihydroxylation.[1679] This reaction is the basis of the *Baeyer test* for the presence of double bonds. The oxidation is compatible with a number of functional groups, including trichloroacetamides.[1680]

Anti hydroxylation can be achieved by treatment with H_2O_2 and formic acid. In this case, epoxidation (**15-50**) occurs first, followed by an S_N2 reaction, which results in overall anti addition:



The same result can be achieved in one step with *m*-chloroperoxybenzoic acid and water.[1681] Overall anti addition can also be achieved by the method of Prévost (the *Prévost reaction*). In this method, the alkene is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is anti and results in a β-halo benzoate (**172**). These can be isolated, and this represents a method of addition of IOCOPh. However, under the normal reaction conditions, the iodine is replaced by a second PhCOO group. This is a nucleophilic substitution reaction, and it operates by the neighboring-group mechanism (p. 446), so the groups are still anti:



172

Hydrolysis of the ester does not change the configuration. The *Woodward modification* of the Prévost reaction is similar, but results in overall syn hydroxylation.[1682] The alkene is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a β-halo ester; the addition is anti and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal S_N2 process,[1683]

so the monoacetate is syn and hydrolysis gives the glycol that is the product of overall syn addition. Although the Woodward method results in overall syn addition, the product may be different from that with OsO_4 or $KMnO_4$, since the overall syn process is from the more-hindered side of the alkene.[1684] Both the Prévost and the Woodward methods[1685] have also been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.[1686] Note that cyclic sulfates can be prepared from alkenes by reaction with PhIO and SO_3•DMF.[1687]

With suitable substrates, addition of two OH groups creates one new stereogenic center from a terminal alkene and two new stereogenic centers from internal alkenes. Addition to alkenes of the form $RCH{=}CH_2$ has been made enantioselective, and addition to $RCH{=}CHR'$ both diastereoselective[1688] and enantioselective,[1689] by using chiral additives or chiral catalysts,[1690] such as **173**, **174** (derivatives of the

naturally occurring quinine and quinuclidine),[1691] along with OsO_4, in what is called *Sharpless asymmetric dihydroxylation*.[1692] Other chiral ligands[1693] have also been used, as well as polymer[1694] and silica-bound[1695] *Cinchona* alkaloids. These amines bind to the OsO_4 *in situ* as chiral ligands, causing it to add asymmetrically.[1696] This has been done both with the stoichiometric and with the catalytic method.[1697] The catalytic method has been extended to conjugated dienes, which give tetrahydroxy products diastereoselectively,[1698] and to conjugated ketones.[1699] Asymmetric dihydroxylation has also been reported with chiral alkenes.[1700] Ligands **173** and **174** not only cause enantioselective addition, but also accelerate the reaction, so that they may be useful even where enantioselective addition is not required.[1701] Although **173** and **174** are not enantiomers, they give enantioselective addition to a given alkene in the opposite sense; for example, styrene predominantly gave the (*R*)-diol with **173**, and the

176

Two phthalazine derivatives,[1704] $(DHQD)_2$PHAL (**175**) and $(DHQ)_2$PHAL (**176**) used in conjunction with an osmium reagent improve the efficiency and ease of use, and are commercial available as AD-mix-β™ (using **175**) and AD-mix-α™ (using **176**). Catalyst **175** is prepared from dihydroquinidine (DHQD) and 1,4-dichlorophthalazine (PHAL), and **176** is prepared from dihydroquinine (DHQ) and PHAL. The actual oxidation labeled AD-mix α- or β-uses **176** or **175**, respectively, mixed with potassium osmate $[K_2OsO_2(OH)_4]$, powdered $K_3Fe(CN)_6$, and powdered K_2CO_3 in an aqueous solvent mixture.[1705] These additives have been used in conjunction with microencapsulated OsO_4,[1705] and polymer bound **175** has been used.[1706] A catalytic amount of flavin has been used.[1707] Both **175**[1708] and **176**[1709] have been used to generate diols with high enantioselectivity. Oxidation of a terminal alkene with AD-mix and then oxidation with TEMPO/NaOCl/$NaOCl_2$ leads to α-hydroxyl carboxylic acids with high enantioselectivity.[1710]

Enantioselective and diastereoselective addition have also been achieved by using preformed derivatives of OsO_4, already containing chiral ligands,[1711] and by the use of OsO_4 on alkenes that have a chiral group elsewhere in the molecule.[1712]

Alkenes can also be oxidized with metallic acetates such as lead tetraacetate[1713] or thallium(III) acetate[1714] to give bis(acetates) of glycols.[1715] Oxidizing agents, such as benzoquinone, MnO_2, or O_2, along with palladium acetate, have been used to convert conjugated dienes to 1,4-diacetoxy-2-alkenes (1,4-addition).[1716] Sodium periodate and sulfuric acid in aqueous media converts conjugated esters to dihydroxy esters.[1717] Diols are also produced by the reaction of a terminal alkyne with Bu_3SnH, followed by ozonolysis, followed by reduction with $BH_3•SMe_2$.[1718] 1,2-Diols are also generated from terminal alkynes by two sequential reactions with a platinum catalyst, and then a palladium catalyst, both with $HSiCl_3$, and a final oxidation with H_2O_2—KF.[1719]

1,2-Dithiols can be prepared from alkenes.[1720]

15-50 Epoxidation (Addition of Oxygen, Oxygen)

***epi*-Oxy-addition**

Alkenes can be epoxidized with many peroxyacids,[1725] of which *m*-chloroperoxybenzoic has been the most often used. The reaction, called the *Prilezhaev reaction*, has wide utility.[1726] Alkyl, aryl, hydroxyl, ester, and other groups may be present, although not amino groups, since these are affected by the reagent. Electron-donating groups increase the rate, and the reaction is particularly rapid with tetraalkyl alkenes. Conditions are mild and yields are high. Other peroxyacids, especially peroxyacetic and peroxybenzoic, are also used; trifluoroperoxyacetic acid[1727] and 3,5-dinitroperoxybenzoic acid[1728] are particularly reactive ones. Transition metal catalysts can facilitate epoxidation of alkenes at low temperatures or with alkenes that may otherwise react sluggishly.[1729] Magnesium monoperoxyphthalate (MMPP)[1730] is commercially available, and has been

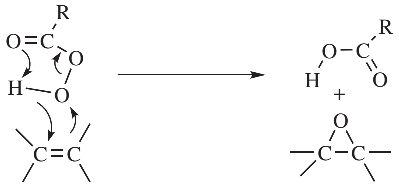
shown to be a good substitute for *m*-chloroperoxybenzoic acid in a number of reactions.[1731]



177

The one-step mechanism involving a transition state, such as **177**,[1731] was proposed by Bartlett:[1732] Evidence for this concerted mechanism is as follows:[1733] (*1*) The reaction is second order. If ionization were the rate-determining step, it would be first order in peroxyacid. (*2*) The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited.[1734] (*3*) Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.[1735] (*4*) The addition is stereospecific (i.e., a trans-alkene gives a trans-epoxide and a cis-alkene a cis-epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate.[1736] However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both cis and trans isomers giving predominantly or exclusively the product where the incoming oxygen is syn to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxy acid.[1737]

In general, peroxides (HOOH and ROOH) are poor regents for epoxidation of simple alkenes since OH and OR are poor leaving groups in the concerted mechanism shown above.[1738] Aqueous hydrogen peroxide epoxidizes alkenes in the presence of fluorous compounds, such as CF_3CH_2OH[1739] or hexafluoroacetone.[1740] Transition-metal catalysts[1741] have been used with alkyl hydroperoxides.[1742] In the presence of other reagents,[1743] peroxides give good yields of the epoxide. These coreagents include dicyclohexylcarbodiimide,[1744] magnesium aluminates,[1745] metalloporphyrins,[1746] hydrotalcite[1747] with microwave irradiation,[1748] fluorous aryl selenides,[1749] and arsines in fluorous solvents.[1750] The catalyst $MeReO_3$[1751] has been used for epoxidation with sodium percarbonate and pyrazole,[1752] with hydrogen peroxide,[1753] and with urea—H_2O_2.[1754] Epoxidation occurs with $FeSO_4$/silica,[1755] and with N_2O and a zinc catalyst.[1756] Epoxidation occurs when alkenes

are treated with oxygen gas, *N*-hydroxyphthalimide, and a mixture of cobalt and molybdenum catalyst.[1757]

Other epoxidation methods are available. Enzymatic epoxidation[1758] and epoxidation with catalytic antibodies[1759] have been reported. Chromyl chloride (CrO_2Cl_2) reacts with alkenes, even at −78°C to give an epoxide and numerous side products including chlorohydrins and dichlorides.[1760] Several mechanisms have been proposed.[1761] Epoxidation has been done in ionic liquids using 10% H_2O_2 with $MnSO_4$[1762] or an iron catalyst.[1763] Hypervalent iodine compounds, such as $PhI(OAc)_2$, in conjunction with a ruthenium catalyst in aqueous media, converts alkenes to epoxides.[1764] This reagent has been used in an ionic liquid with a manganese catalyst.[1765]

Dioxiranes,[1766] such as dimethyl dioxirane (**178**),[1767] either isolated or generated *in situ*,[1768] are important epoxidation reagents. With dimethyloxirane, C—H insertion reactions can occur preferentially.[1769] The reaction with alkenes is rapid, mild, safe, and a variety methods have been developed using an oxidant as a coreagent. The most commonly used coreagent is probably potassium peroxomonosulfate ($KHSO_5$). Oxone® (2 $KHSO_5$•$KHSO_4$•K_2SO_4) is a common source of $KHSO_5$. Oxone® reacts with ketones[1770] and sodium bicarbonate to convert an alkene

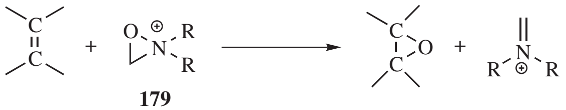
to an epoxide. Oxone® also converts alkenes to epoxides in the presence of certain additives, such as *N,N*-dialkylalloxans.[1771] Oxone, usually with hydrogen peroxide or another similar oxidant, can be used with chiral ketones[1772] or aldehydes to convert alkenes to chiral, nonracemic epoxides.[1773] Chiral dioxiranes have reportedly given nonracemic epoxides.[1774] Hydrogen peroxide, in the presence of chiral ketones in acetonitrile (or other nitrile solvents), probably converts alkenes to epoxides with good enantioselectivity by *in situ* generation of dioxirane.[1775] Epoxidation does not occur in good yields with these reagents in most other solvents, and it is suggested that the active agent that generates dioxirane is peroxyimidic acid MeC(=NH)OOH.[1776] Note that benzaldehyde with Chloramine-M[1777] will convert alkenes to epoxides.[1778] Amines, including chiral amines can be similarly used with aldehydes with aqueous sodium bicarbonate.[1779]

178

oxirene



179

Oxone® oxidizes iminium salts to an oxaziridinium intermediate **179**, which can transfer oxygen to an alkene to form an epoxide and regenerate the iminium salt.[1780]

This variation has been applied to asymmetric[1781] epoxidations using chiral iminium salt precursors.[1782]

Although cis–trans isomerization of epoxides is not formally associated with this section, it is clearly a potential problem in the conversion of an alkene to an epoxide. There are several catalysts for this process.[1783]

It would be useful if triple bonds could be similarly epoxidized to give oxirenes, but they are not stable compounds.[1784] Two of them have been trapped in solid argon matrices at very low temperatures, but they decayed on warming to 35 K.[1785] Oxirenes probably form in the reaction,[1786] but react further before they can be isolated. Note that oxirenes bear the same relationship to cyclobutadiene that furan does to benzene and may therefore be expected to be antiaromatic (see p. 38).

Conjugated dienes can be epoxidized (1,2-addition), although the reaction is slower than for corresponding alkenes, but α,β-unsaturated ketones do not generally give epoxides when treated with peroxyacids.[1787] The epoxidation of α,β-unsaturated ketones with hydrogen peroxide under basic conditions is known as the *Waits–Scheffer epoxidation*, discovered in 1921.[1788] This fundamental reaction has been extended to α,β-unsaturated ketones (including quinones), aldehydes, and sulfones.[1789] This is a nucleophilic addition by a Michael-type mechanism, involving attack by HO_2^-:[1790] This reaction is another example of 1,4-addition of a heteroatom containing species as discussed in **15-31**.

α,β-Unsaturated compounds can be epoxidized alkyl hydroperoxides and a base,[1791] or with H_2O_2 and a base or heteropoly acids.[1792] The reaction has been done in D_2O using sodium bicarbonate with hydrogen peroxide.[1793] The reaction has been done with LiOH and polymer-bound quaternary ammonium salts.[1794] Epoxides can also be prepared by treating alkenes with oxygen or with an alkyl peroxide[1795] catalyzed by a complex of a transition metal such as V, Mo, Ti, La,[1796] or Co.[1797] The reaction with oxygen, which can also be carried out without a catalyst, is probably a free-radical process.[1798] Conjugated ketones are oxidized to epoxy-ketones with $NaBO_3$ and tetrahexylammonium hydrogen sulfate,[1799] KF-Al_2O_3/*tert*-butyl hydroperoxide.[1800] α,β-Unsaturated esters react normally to give glycidic esters.[1801] When a carbonyl group is elsewhere in the molecule but not conjugated with the double bond, the Baeyer–Villiger reaction (**18-19**) may compete. Allenes[1802] are converted by peroxyacids to allene oxides[1803] or spiro dioxides, both of which species can in certain cases be isolated[1804] but more often are unstable under the reaction conditions and react further to give other products.[1805]

Asymmetric Weitz–Scheffer epoxidation is commonly used for the epoxidation of electron-poor alkenes. Cinchona-derived phase-transfer catalysts, initially used

by Wynberg, are now common.[1806] Enantioselectivities can be significantly improved by changes of the catalyst structure as well as the type of oxidant.[1807] A Yb-BINOL complex, with *t*-BuOOH led to epoxidation of conjugated ketones with high asymmetric induction,[1808] as did a mixture of NaOCl and a *Cinchona* alkaloid.[1809] Other enantioselective methods include treatment with diethylzinc, O_2, in the presence of a chiral amino-alcohol, to give the epoxy-ketone.[1810] Similarly, treatment with aqueous NaOCl[1811] or with an alkyl hydroperoxide[1812] and a chiral phase-transfer agent leads to chiral nonracemic epoxy-ketones.

Another important asymmetric epoxidation of a conjugated systems is the reaction of alkenes with polyleucine, DBU and urea—H_2O_2, giving an epoxy-carbonyl compound with good enantioselectivity.[1813] The hydroperoxide anion epoxidation of conjugated carbonyl compounds with a polyamino acid, such as poly-L-alanine or poly-L-leucine is known as the *Juliá–Colonna epoxidation.*[1814] Epoxidation of conjugated ketones to give nonracemic epoxy-ketones was done with aq. NaOCl and a Cinchona alkaloid derivative as catalyst.[1815] A triphasic phase-transfer catalysis protocol has also been developed.[1816] β-Peptides have been used as catalysts in this reaction.[1817]

Allylic alcohols can be converted to epoxy-alcohols with *tert*-butylhydroperoxide on molecular sieves,[1818] or with peroxy acids.[1819] The addition of an appropriate chiral ligand to the metal-catalyzed hydroperoxide epoxidation of allylic alcohols leads to high enantioselectivity. This important modification is

known as the *Sharpless asymmetric epoxidation*,[1820] where allylic alcohols are converted to optically active epoxides with excellent enantioselectivity by treatment with *t*-BuOOH, titanium tetraisopropoxide and optically active diethyl tartrate.[1821] The $Ti(OCHMe_2)_4$ and diethyl tartrate can be present in catalytic amounts (15–10 mol%) if molecular sieves are present.[1822] Polymer-supported catalysts have also been reported.[1823] Both (+) and (−) diethyl tartrate are readily available, so either enantiomer of the product can be prepared. The method has been successful for a wide range of primary allylic alcohols, including substrates where the double bond is mono-, di-, tri-, and tetrasubstituted,[1824] and is highly useful in natural product synthesis. The mechanism of the Sharpless epoxidation is believed to involve attack on the substrate by a compound[1825] formed from the titanium alkoxide and the diethyl tartrate to produce a complex that also contains the substrate and the *t*-BuOOH.[1826]

Ordinary alkenes (without an allylic OH group) do not give optically active alcohols by the Sharpless protocol because binding to the catalyst is necessary for enantioselectivity. Simples alkenes can be epoxidized enantioselectively with sodium hypochlorite (NaOCl, commercial bleach) and an optically active manganese-complex catalyst.[1827] An important variation of this oxidation uses a manganese–salen complex[1828] with various oxidizing agents, in what is called

the *Jacobsen–Katsuki reaction*.[1829] Apart from the commonly used NaOCl, urea—H_2O_2 has been used.[1830] With this reaction, simple alkenes can be epoxidized with high enantioselectivity.[1831] The mechanism of this reaction has been examined.[1832] Radical intermediates have been suggested for this reaction,[1833] A polymer-bound $Mn^{(III)}$–salen complex, in conjunction with NaOCl, has been used for asymmetric epoxidation.[1834] Chromium–salen complexes[1835] and ruthenium–salen complexes[1836] have been used for epoxidation. Manganese porphyrin complexes have also been used.[1837] Cobalt complexes give similar results.[1838] A related epoxidation reaction used an iron complex with molecular oxygen and isopropanal.[1839] Nonracemic epoxides can be prepared from racemic epoxides with salen–cobalt(II) catalysts following a modified procedure for kinetic resolution.[1840]

In a different type of reaction, alkenes are photooxygenated (with singlet O_2, see **14-7**) in the presence of a Ti, V, or Mo complex to give epoxy alcohols, such as **180**, formally derived from allylic hydroxylation followed by epoxidation.[1841] In other cases, modification of the procedure gives simple epoxidation.[1842] Alkenes react with aldehydes and oxygen, with palladium-on-silica[1843] or a ruthenium catalyst,[1844]

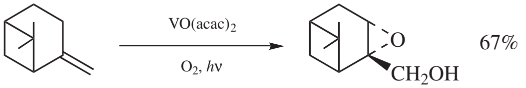
to give the epoxide.



180

Thiiranes can be prepared directly from alkenes using specialized reagents.[1845] Thiourea with a tin catalyst gives the thiirane, for example.[1846] Interestingly, internal alkynes were converted to 1,2-dichorothiiranes by reaction with S_2Cl_2 (sulfur monochloride).[1847] It is noted that epoxides are converted to thiiranes with ammonium thiocyanate and a cerium complex.[1848] A trans-thiiration reaction occurs with a molybdenum catalyst, in which an alkene reacts with styrene thiirane to give the new thiirane.[1849]

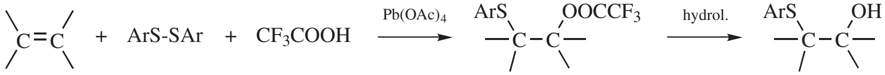
15-51 Hydroxysulfenylation (Addition of Oxygen, Sulfur)

Hydroxy-arylthio-addition (overall transformation)



A hydroxy and an arylthio group can be added to a double bond by treatment with an aryl disulfide and lead tetraacetate in the presence of trifluoroacetic acid.[1850] Manganese and copper acetates have been used instead of $Pb(OAc)_4$.[1851] Addition of the groups OH and RSO has been achieved by treatment of alkenes with O_2 and a thiol RSH.[1852] Two RS groups were added, to give *vic*-dithiols, by treatment of the alkene with a disulfide RSSR and BF_3-etherate.[1853] This reaction

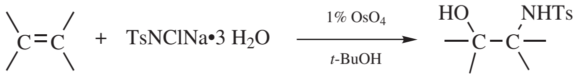
has been carried out internally.[1854] In a similar manner, reaction of alkenes with ceric ammonium nitrate, diphenyl diselenide in methanol leads to vicinally substituted phenylselenyl methyl ethers.[1855] Dimethyl diselenide adds to alkenes to form vicinal bis-methylselenyl compounds, in the presence of tin tetrachloride.[1856]

Halo-ethers can be formed by the reaction of alkenyl alcohols with various reagents. Hept-6-en-1-ol reacts with $(\text{collidine})_2\text{I}^+\text{PF}_6^-$, for example, to form 2-iodomethyl-1-oxacycloheptane.[1857]

15-52 Oxyamination (Addition of Oxygen, Nitrogen)

Tosylamino-hydroxy-addition



N-Tosylated β-hydroxy alkylamines (which can be easily hydrolyzed to β-hydroxyamines[1858]) can be prepared[1859] by treatment of alkenes with the trihydrate of Chloramine-T (*N*-chloro-*p*-toluenesulfonamide sodium salt)[1566] and a catalytic amount of OsO_4.[1860] In some cases, yields can be improved by the use of phase-transfer catalysis.[1861] The reaction has been carried out enantioselectively.[1862] Alkenes can be converted to amido alcohols enantioselectivity by modification of this basic scheme. The *Sharpless asymmetric aminohydroxylation* employs a catalyst consisting of *Cinchona* alkaloid derived ligands and an osmium species in combination with a stoichiometric nitrogen source that also functions as the oxidant.[1863] The reaction of a carbamate with $(\text{DHQ})_2$PHAL (**176**) and the osmium compound, with NaOH and *tert*-butyl hypochlorite, leads to a diastereomeric mixture of amido alcohols **181** and **182**, each formed with high enantioselectivity.[1864] In general, the nitrogen adds to the less sterically hindered carbon of the alkene to give the major product. *N*-Bromoamides, in the presence of a catalytic amount of $(\text{DHQ})_2$PHAL

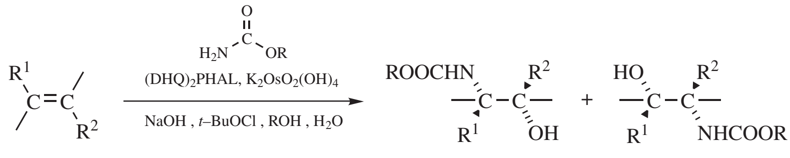
and LiOH converts conjugated esters to β-amido-α-hydroxy esters with good enantioselectivity.[1865] In another procedure, certain β-hydroxy secondary alkylamines can be prepared by treatment of alkenes with the osmium compound *t*-Bu—N=OsO_3, followed by reductive cleavage with $LiAlH_4$ of the initially formed osmic esters.[1866] It is presumed that Ts—N=OsO_3 is an intermediate in the Chloramine-T reaction. Another oxyamination reaction involves treatment of a palladium complex of the alkene with a secondary or primary amine, followed by lead tetraacetate or another oxidant.[1867]



181 **182**

The organolanthanide-catalyzed alkene hydroamination has been reported.[1868] With this approach, amino alkenes (not enamines) can be cyclized to form cyclic amines,[1869] and amino alkynes lead to cyclic imine.[1870] The use of synthesized *C*-1[1871] and *C*-2 symmetric[1872] chiral organolanthanide complexes give the amino alcohol with good enantioselectivity.

β-Amino alcohols can be prepared by treatment of an alkene with a reagent prepared from HgO and HBF_4 along with aniline to give an aminomercurial compound PhHN—C—C—$HgBF_4$ (aminomercuration; see **15-7**) which is hydrolyzed

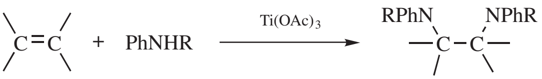
to PhHN–C–C–OH.[1873] The use of an alcohol instead of water gives the corresponding amino ether. β-Azido alcohols are prepared by the reaction of an alkene with $Me_3SiOOSiMe_3$, Me_3SiN_3, and 20% $(Cl_2SnO)_n$, followed by treatment with aqueous acetic acid.[1874]

OS **VII**, 223, 375.

15-53 Diamination (Addition of Nitrogen, Nitrogen)

Di(alkylarylamino)-addition



Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.[1875] The reaction is not successful for primary aliphatic amines. In another procedure, alkenes can be diaminated by treatment with the osmium compounds R_3NOsO (R = *t*-Bu) and R_2NOsO_2,[1876] analogous to the osmium compound mentioned at **15-52**.[1877] The palladium-promoted method of **15-52** has also been extended to diamination.[1878] Alkenes can also be diaminated[1879] indirectly by treatment of the aminomercurial compound mentioned in **15-52** with a primary or secondary aromatic amine.[1880] The reaction of an alkene with *N*-arylsulfonyl dichloroamines, $ArSO_2NCl_2$, followed by reaction with aqueous Na_2SO_3, gives the *anti-vic*-diacetamde.[1881]

Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid, C=C + NaN_3 + PhIO → N_3—C—C —N_3.[1882]

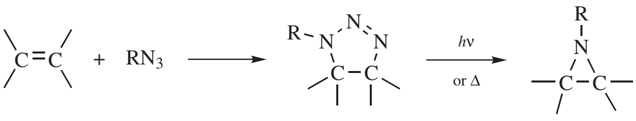
15-54 Formation of Aziridines (Addition of Nitrogen, Nitrogen)

***epi*-Arylimino-addition**, and so on.



Triazoline

Aziridines can be prepared directly from double-bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.[1883] The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO_2, as well as other groups. The reaction can take place by at least two pathways.

In one pathway a 1,3-dipolar addition (**15-58**) takes place to give a triazoline (which can be isolated), followed thermal by extrusion of nitrogen (**17-34**). Evidence for the nitrene pathway is most compelling for R = acyl groups. In the other, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to that of carbene addition (**15-64**). Sulfonyloxy amines, such as $ArSO_2ONHCO_2Et$, form an aziridine when treated with CaO in the presence of a conjugated carbonyl compound.[1884] In the presence of copper,[1885] cobalt,[1886] or rhodium complexes,[1887] ethyl diazoacetate adds to imines to give aziridines. Diazirines (p. 288) with *n*-butyllithium converted conjugated amides to the α,β-aziridino amide.[1888] Calcium oxide has also been used to generate the nitrene,[1889] including nitrene precursors that have an attached chiral ester.[1890] Other specialized reagents have also been used.[1891] As discussed on p. 293, singlet nitrenes add stereospecifically while triplet nitrenes do not. Diphenyl sulfimide (Ph_2SNH) converts

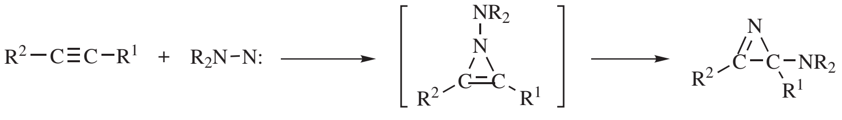
Michael-type substrates to the corresponding aziridines.[1892] Aminonitrenes (R_2NN:) have been shown to add to alkenes[1893] to give *N*-substituted aziridines and to triple bonds to give 1-azirines, which arise from rearrangement of the initially formed 2-azirines.[1894] Like oxirenes (see **15-50**), 2-azirines are unstable, probably because of anti-aromaticity. 1-Azirines can be reduced to give chiral aziridines.[1895]



2-Azirine 1-Azirine

An alternative preparation of aziridines reacts an alkene with iodine and chloramine-T, generating the corresponding *N*-tosyl aziridine.[1896] Chloramine T and NBS also gives the *N*-tosyl aziridine,[1897] and bromamine-T ($TsNBr^-Na^+$) has been used in a similar manner,[1898] and also TsNIK.[1899] Diazoalkanes react with imines to give aziridines.[1900] Another useful reagent is NsN=IPh, which reacts with alkenes in the presence of rhodium compounds[1901] or $Cu(OTf)_2$[1902] to give *N*-Ns aziridines. Other sulfonamide reagents can be used,[1903] including PhI=NTs.[1904] Enantioselective aziridination is possible using this reaction with

chiral ligands.[1905] This reagent has been used in ionic liquids with a copper catalyst.[1906] Such reactions are catalyzed by palladium[1907] and methyl trioxorhenium ($MeReO_3$) can be used in these reactions.[1908] Manganese–salen catalysts have also been used with this reagent.[1909] A nitrido manganese–salen complex was also used with ditosyl anhydride, converting a conjugated diene to an allylic *N*-tosylaziridine.[1910]

Nitrenes can also add to aromatic rings to give ring-expansion products analogous to those mentioned in **15-62**.[1911]

OS **VI**, 56.

15-55 Aminosulfenylation (Addition of Nitrogen, Sulfur)

Arylamino-arylthio-addition

An amino and an arylthio group can be added to a double bond by treatment with a sulfenanilide PhSNHAr in the presence of BF_3-etherate.[1912] The addition is anti, and the mechanism probably involves a thiiranium ion.[1913] In another aminosulfenylation procedure, the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate ($MeSSMe_2\ BF_4^-$) and ammonia or an amine,[1914] the latter acting as a nucleophile. This reaction was extended to other nucleophiles:[1915] N_3^-,[1916]

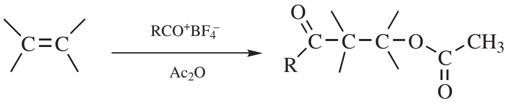
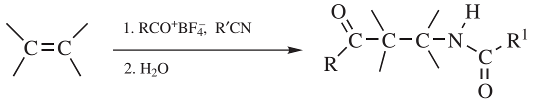
NO_2^- CN^-, ^-OH, and ^-OAc to give MeS–C–C–A, where A = N_3, NO_2, CN, OH, and OAc, respectively. An RS (R = alkyl or aryl) and an NHCOMe group have been added in an electrochemical procedure.[1917]

15-56 Acylacyloxylation and Acylamidation (Addition of Oxygen, Carbon, or Nitrogen, Carbon)

Acyl-acyloxy-addition

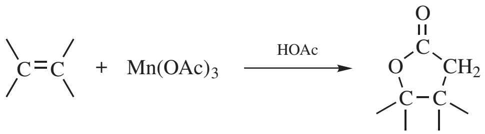


An acyl and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.[1918] As expected, the addition follows Markovnikov's rule, with the electrophile Ac^+ going to the carbon with more hydrogens. In an analogous reaction, an acyl and an amido group can be added to give **183**, if a nitrile is used in place of the anhydride. Similarly, halo acetoxylation is known.[1919] This reaction has also been carried out on triple bonds, to give the unsaturated analogs of **183** (syn addition).[1920]



183

15-57 The Conversion of Alkenes to γ-Lactones (Addition of Oxygen, Carbon)



This reaction is clearly related to forming esters and lactones by reaction of carboxylic acids with alkenes (**15-6**), but the manganese reagent leads to

differences. Alkenes react with manganese(III) acetate to give γ-lactones.[1921] The mechanism is probably free radical, involving addition of •CH_2COOH to the double bond. Ultrasound improves the efficiency of the reaction.[1922] In a related reaction, cyclohexene reacted with $MeO_2CCH_2CO_2K$ and $Mn(OAc)_3$ to give an α-carbomethoxy bicyclic lactone.[1923] The use of dimethyl malonate and ultrasound in this reaction gave the same type of product.[1924] Lactone formation has also been accomplished by treatment of alkenes with α-bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,[1925] and with alkylidene chromium pentacarbonyl complexes.[1926] Alkenes can also be converted to γ- lactones by indirect routes.[1927] Chromium–carbene complexes add to alkenes to give β-lactones using ultrasound.[1928]

An intramolecular variation of this reaction is known, involving amides, which generates a lactam.[1929]

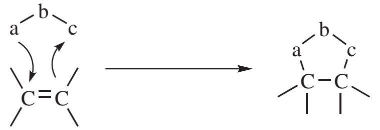
15-58 1,3-Dipolar Addition (Addition of Oxygen, Nitrogen, Carbon)



184

There are a large group of reactions ([3 + 2]-cycloadditions) in which five-membered heterocyclic compounds are prepared by addition of 1,3-dipolar compounds to double bonds. This reaction is quite useful in the synthesis of alkaloids,[1930] including asymmetric syntheses.[1931] These dipolar compounds have a

sequence of three atoms *a–b–c*, of which *a* has a sextet of electrons in the outer shell and *c* an octet with at least one unshared pair (see Table 15.3).[1932] The reaction can then be formulated as shown to generate **184**. Note that the initial reaction of potassium permanganate (**15-48**) occurs by [3 + 2]-cycloaddition to give a manganate ester (**171**).[1933] [3+2]-Cycloadditions occur with other metal oxides.[1934] Hydrazones have also been reported to give [3 + 2]-cycloadditions.[1935]

1,3-Dipoles of the type shown in Table 15.3 have an atom with six electrons in the outer shell, which is usually unstable, and such compounds will delocalize the change to alleviate this electronic arrangement (they are resonance stabilized). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond on the sextet atom and the other canonical form has a triple bond on that atom:

$$\overset{\ominus}{a}-b=\overset{\oplus}{c}- \quad \longleftrightarrow \quad \overset{\ominus}{a}-b\equiv\overset{\oplus}{c}-$$

TABLE 15.3. Some Common 1,3-Dipolar Compounds

Type 1		
	Azide	$R-\overset{\ominus}{N}-N=\overset{\oplus}{N} \longleftrightarrow R-\overset{\ominus}{N}-\overset{\oplus}{N}\equiv N$
	Diazoalkane[1936]	$R_2\overset{\ominus}{C}-N=\overset{\oplus}{N} \longleftrightarrow R_2\overset{\ominus}{C}-\overset{\oplus}{N}\equiv N$
	Nitrous oxide	$\overset{\ominus}{O}-N=\overset{\oplus}{N} \longleftrightarrow \overset{\ominus}{O}-\overset{\oplus}{N}\equiv N$
	Nitrile imine[1937]	$R-\overset{\ominus}{N}-N=\overset{\oplus}{C}R' \longleftrightarrow R-\overset{\ominus}{N}-\overset{\oplus}{N}\equiv CR'$
	Nitrile ylid[1938]	$R_2\overset{\ominus}{C}-N=\overset{\oplus}{C}R' \longleftrightarrow R_2\overset{\ominus}{C}-\overset{\oplus}{N}\equiv CR'$
	Nitrile oxide[1939]	$\overset{\ominus}{O}-N=\overset{\oplus}{C}R \longleftrightarrow \overset{\ominus}{O}-\overset{\oplus}{N}\equiv CR$
Type 2		
	Azomethine imine	$R_2\overset{\ominus}{C}-\underset{R^2}{N}-\overset{\oplus}{N}R' \longleftrightarrow R_2\overset{\ominus}{C}-\underset{R^2}{\overset{\oplus}{N}}=NR'$
	Azoxy compound	$\overset{\ominus}{O}-\underset{R}{N}-\overset{\oplus}{N}R' \longleftrightarrow \overset{\ominus}{O}-\underset{R}{\overset{\oplus}{N}}=NR'$
	Azomethine ylid[1940]	$R_2\overset{\ominus}{C}-\underset{R^2}{N}-\overset{\oplus}{C}R'_2 \longleftrightarrow R_2\overset{\ominus}{C}-\underset{R^2}{\overset{\oplus}{N}}=CR'_2$
	Nitrone	$\overset{\ominus}{O}-\underset{R'}{N}-\overset{\oplus}{C}R_2 \longleftrightarrow \overset{\ominus}{O}-\underset{R'}{\overset{\oplus}{N}}=CR_2$
	Carbonyl oxide[1941]	$\overset{\ominus}{O}-O-\overset{\oplus}{C}R_2 \longleftrightarrow \overset{\ominus}{O}-\overset{\oplus}{O}=CR_2$
	Ozone	$\overset{\ominus}{O}-O-\overset{\oplus}{O} \longleftrightarrow \overset{\ominus}{O}-\overset{\oplus}{O}=O$

If we limit ourselves to the first row of the periodic table, *b* can only be nitrogen, *c* can be carbon or nitrogen, and *a* can be carbon, oxygen, or

nitrogen; hence there are six types. Among these are azides ($a = b = c =$ N) and diazoalkanes.

2. Those in which the dipolar canonical form has a single bond on the sextet atom and the other form has a double bond:

Here *b* can be nitrogen or oxygen, and *a* and *c* can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example, N–N–C is only another form of C–N–N. Examples are shown in Table 15.3.

Of the 18 systems, some of which are unstable and must be generated *in situ*,[1942] the reaction has been accomplished for at least 15, but not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds[1943]). Not all alkenes undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the Diels–Alder reaction (**15-60**). The addition is stereospecific and syn, and the mechanism is probably a one-step concerted process,[1944] as illustrated above,[1945] largely controlled by Frontier Molecular Orbital considerations.[1946] In-plane aromaticity has been invoked for these dipolar cycloadditions.[1947] As expected for this type of mechanism, the rates do not vary much with changes in solvent,[1948] although rate acceleration has been observed in ionic liquids.[1949] Nitrile oxide cycloadditions have also been done in supercritical carbon dioxide.[1950] There are no simple rules

covering orientation in 1,3-dipolar additions. The regioselectivity has been explained by molecular-orbital treatments,[1951] where overlap of the largest orbital coefficients of the atoms forming the new bonds leads to the major regioisomer. When the 1,3-dipolar compound is a thiocarbonyl ylid ($R_2C{=}S^+{-}CH_2^-$) the addition has been shown to be nonstereospecific with certain substrates but stereospecific with others, indicating a nonsynchronous mechanism in these cases, and in fact, a diionic intermediate (see mechanism *c* on p. 1224) has been trapped in one such case.[1952] In a theoretical study of the 1,3-dipolar cycloadditions (diazomethane and ethene; fulminic acid [H—C≡N—O] and ethyne),[1953] calculations based on valence bond descriptions suggest that many concerted 1,3-dipolar cycloaddition reactions follow an electronic heterolytic mechanism where the movement of well-identifiable orbital pairs are retained along the entire reaction path from reactants to product.[1954]

An antibody-catalyzed [3 + 2]-cycloaddition has been reported.[1955] Metal assisted dipolar additions are also known.[1956]

Many of the cycloadducts formed from the dipoles in Table 15.3 are unstable, leading to other products. The reaction of alkyl azides with alkenes generates triazolines (**15-54**), which extrude nitrogen (N≡N) upon heating or photolysis to give an aziridine.

[3 + 2]-Cycloaddition reactions occur intramolecularly to generate bicyclic and polycyclic compounds.[1957] The intramolecular cycloaddition of azomethine imines give bicyclic pyrrazolidines for example.[1958] When diazoalkanes, including diazo acetates such as N_2CHCO_2Et react with an alkene and a chromium catalyst the initially formed product is a five-membered ring, a pyrazoline. Pyrazolines are generally unstable and extrusion of nitrogen leads to a cyclopropane.[1959]

There are many cases where the [3 + 2]-cycloaddition leads to cycloadducts with high enantioselectivity.[1960] Cycloaddition of diazo esters with a cobalt catalyst having a chiral ligand leads to cyclopropane derivatives with good enantioselectivity.[1961]

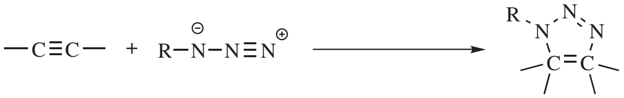
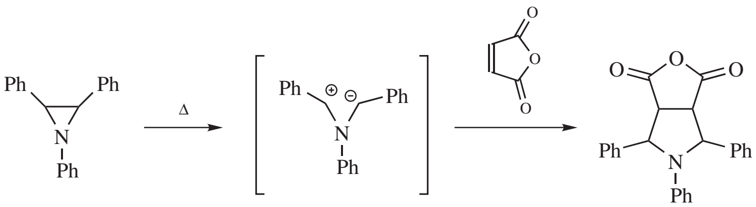
Cycloaddition of nitrones and pyrazolinones with a copper catalyst and a chiral ligand leads to pyrrolidine derivatives with good enantioselectivity.[1962]

Conjugated dienes generally give exclusive 1,2-addition, although 1,4 addition (a [3 + 4]-cycloaddition) has been reported.[1963] Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.[1964] For example, azides react to give triazoles, **185**.



185

The 1,3-dipolar reagent can in some cases be generated by the *in situ* opening of a suitable three-membered ring system. For example, aziridines open to give a zwitterion, such as **186**, which can add to activated double bonds to give pyrrolidines.[1965]



186

Aziridines also add to C≡C triple bonds as well as to other unsaturated linkages, including C=O, C=N, and C≡N.[1966] In some of these reactions it is a C–N bond of the aziridine that opens rather than the C–C bond.

For other [3 + 2]-cycloadditions, see **15-59**.

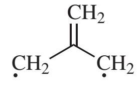
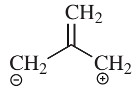
15-59 All-Carbon [3 + 2]-Cycloadditions[1968]

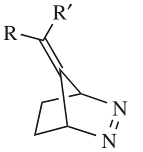
Several methods have been reported for the formation of cyclopentanes by [3 + 2]-cycloadditions.[1969] Heating a conjugated ketones wtih trialkylphosneines genrates an intermdiate that adds to conjugated alkynes.[1970] One type involves reagents that produce intermediates **187** or **188**.[1971] A synthetically useful example[1972] uses 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate (**191**) (which is commercially available) and a palladium or other transition-metal catalyst to generate **187** or **188**, which adds to double bonds, to give, in



187



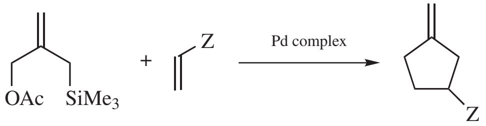
188



189

190

good yields, cyclopentanes with an exocyclic double bond. Note that **95** also reacts with *N*-tosyl aziridines, with 20% *n*-butyllithium and 10% of $Pd(OAc)_2$, to give a vinylidene piperidine derivative.[1973] Similar or identical intermediates generated from bicyclic azo compounds **189** (see **17-34**) or methylenecyclopropane **190**[1974] also add to activated double bonds. With suitable substrates the addition can be enantioselective.[1975]



191

In a different type of procedure, [3 + 2]-cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.[1976] For example, α-methylstyrene adds to stilbene on treatment with the strong base LDA.[1977]

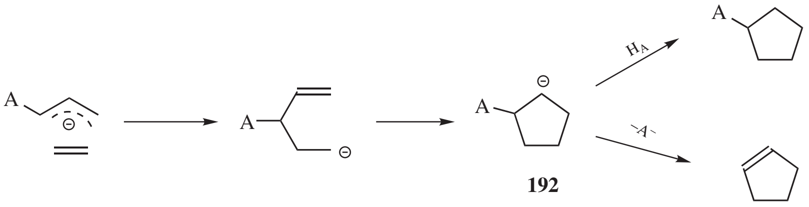
[1977]Eidenschink, R.; Kauffmann, T. *Angew. Chem. Int. Ed.* ***1972***, *11*, 292.

The mechanism can be outlined as



192

In the case above, **192** is protonated in the last step by the acid HA, but if the acid is omitted and a suitable nucleofuge is present, it may leave, resulting in a cyclopentene.[1978] In these cases the reagent is an allylic anion, but similar [3 + 2]-cycloadditions involving allylic cations have also been reported.[1979]

OS **VIII**,173, 347.

15-60 The Diels–Alder Reaction

(4 + 2)*cyclo*-Ethylene-1/4/addition or **(4 + 2)*cyclo*-[Bu*t*-2-ene-1,4-diyl]-1/2/ addition**, and so on.

In the prototype *Diels–Alder reaction* the double bond of an alkene adds 1,4 to a conjugated diene (a [4 + 2]-cycloaddition),[1980] so the product is always a cyclohexene. The cycloaddition is not limited to alkenes or to dienes (see **15-61**), but the substrate that reacts with the diene is called a *dienophile*. The reaction is of

very broad scope[1981] and reactivity of dienes and dienophiles can be predicted based on analysis of the HOMOs[1982] and LUMOs of these species (frontier molecular orbital theory).[1983] Ethylene and simple alkenes make poor dienophiles, unless high temperatures and/or pressures are used. Most dienophiles are of the form —C=C—Z or Z—C=C—Z′, where Z and Z′ are electron-withdrawing groups,[1984] such as CHO, COR,[1985] COOH, COOR, COCl, COAr, CN,[1986] NO_2,[1987] Ar, CH_2OH, CH_2Cl, CH_2NH_2, CH_2CN, CH_2COOH, halogen, $PO(OEt)_2$,[1988] or C=C. In the last case, the dienophile is itself a diene.[1989] Particularly common dienophiles are maleic anhydride[1990] and quinones.[1991] Triple bond compounds (–C≡C–Z or Z–C≡C– Z′)

193

may be dienophiles,[1992] generating nonconjugated cyclohexadienes (**193**), and this reaction can be catalyzed by transition-metal compounds.[1993] Allenes react as dienophiles, but without activating groups are very poor dienophiles.[1994]

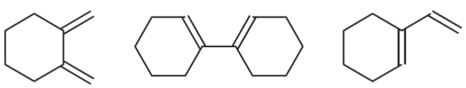
Ketenes, however, do not undergo Diels–Alder reactions.[1995] Benzynes, although not isolable, act as dienophiles and can be trapped with dienes,[1996] for example,

194

The low reactivity of simple alkenes can be overcome by incorporating an electron-withdrawing group to facilitate the cycloaddition, but a group that can be removed after the cycloaddition. An example is phenyl vinyl sulfone $PhSO_2CH{=}CH_2$.[1997] The $PhSO_2$ group can be easily removed with Na–Hg after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide ($PhSOCH{=}CH_2$) can be used as a synthon for acetylene.[1998] In this case PhSOH is lost from the sulfoxide product (**17-12**).



195 **196** **197**

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it.[1999] For the dienophile it is just the reverse: donating groups decrease the rate, and withdrawing groups increase it. The cisoid conformation is required for the cycloaddition,[2000] and acyclic dienes are conformationally mobile so the cisoid conformation will be available. Cyclic dienes, in which the cisoid conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the cisoid conformation by rotation.[2001] Dienes can be open-chain, inner-ring (e.g., **194**), outer-ring[2002] (e.g., **195**), across

[1995]Ketenes react with conjugated dienes to give 1,2-addition (see **15-49**).

rings (e.g., **196**), or inner-outer (e.g., **197**), except that they may not be frozen into a transoid conformation (see p. 1201). They need no special activating groups, and nearly all conjugated dienes undergo the reaction with suitable dienophiles.[2003]

In most Diels–Alder reactions, no catalyst is needed, but Lewis acids are effective catalysts in many cases,[2004] particularly those in which Z in the dienophile is a C=O or C=N group. A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of endo addition,[2005] and, in the case of enantioselective reactions, the extent of enantioselectivity. It has been shown that $InCl_3$ is an effective catalyst for aqueous Diels–Alder reactions,[2006] which is suitable for ionic Diels–Alder reactions,[2007] and there are other Lewis acid catalysts that are effective in water.[2008] Brønsted acids have also been used to accelerate the rate of the Diels–Alder reaction.[2009] Lanthanum triflate [$La(OTf)_3$] has been reported as a reusable catalyst[2010] and Me_3SiNTf_2 has been used as a green Lewis acid catalyst.[2011] Cationic Diels–Alder catalysts have been developed, particularly oxazaborolidine catalysts.[2012] Some Diels–Alder reactions can also be catalyzed by the addition of a stable cation radical,[2013] for

on the reaction has been examined[2030] as has micellular effects.[2031] Another alternative reaction medium is the use of 5 *M* $LiClO_4$ in Et_2O as solvent,[2032] An alternative to lithium perchlorate in ether is lithium triflate in acetonitrile.[2033] The addition of HPO_4^-– to an aqueous ethanol solution has also been shown to give an small rate enhancement.[2034] This appears to be the only case where an anion is responsible for a rate enhancement. The *retro*-Diels–Alder reaction has also been done in water.[2035]

It is noted that the Diels–Alder reaction has been done with supercritical CO_2[2036] and with supercritical water[2037] as solvents. Diels–Alder reactions on solid supports have also been reported,[2038] and zeolites have been used in conjunction with catalytic agents.[2039] Alumina has been used to promote Diels–Alder reactions.[2040] Diels–Alder reactions can be done in ionic liquids,[2041] including asymmetric Diels–Alder reactions.[2042]

When an unsymmetrical diene adds to an unsymmetrical dienophile, regioisomeric products (not counting stereoisomers) are possible. Rearrangements have been encountered in some cases.[2043] In simple cases, 1-substituted dienes give cyclohexenes with a 1,2- and a 1,3- substitution pattern. 2-Substituted dienes

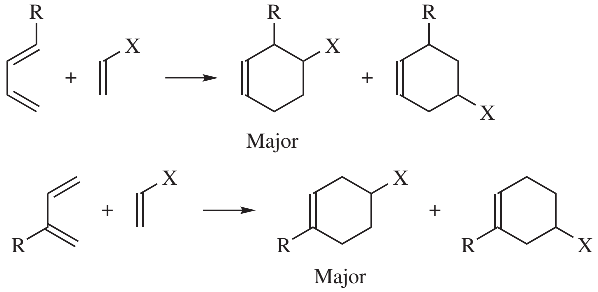
lead to 1,4- and 1,3-disubstituted products.



Although mixtures are often obtained, usually one predominates, the one indicated above, but selectivity depends on the nature of the substituents on both diene and alkene. This regioselectivity, in which the "ortho" or "para" product is favored over the "meta," has been explained by molecular-orbital considerations.[2044] When $X = NO_2$, regioselectivity to give the "ortho" or "para" product was very high at room temperature, and this method, combined with subsequent removal of the NO_2 (see **19-67**) has been used to perform regioselective Diels–Alder reactions.[2045]

The stereochemistry of the Diels–Alder reaction can be considered from several aspects:[2046]

1. With respect to the dienophile, the addition is stereospecifically syn, with very few exceptions.[2047] This means that groups that are cis in the alkene will be cis in the cyclohexene ring, (A—B and C—D) and groups that are trans in the alkene will be trans in the cyclohexene ring (A—D and C—B).

2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and syn. Thus, *trans*, *trans*-1,4-diphenylbutadiene gives *cis*-1,4-diphenylcyclohexene derivatives. This

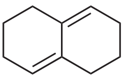
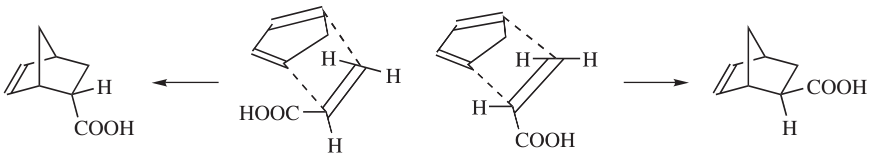
selectivity is predicted by disrotatory motion of the substituent in the transition state[2048] of the reaction (see **18-27**).

3. The diene must be in the cisoid conformation. If it is frozen into the transoid conformation, as in **198**, the reaction does not take place. The diene either must be frozen into the cisoid conformation or must be able to achieve it during the reaction.



198

4. When the diene is cyclic, there are two possible ways in which addition can occur if the dienophile is not symmetrical. The larger side of the dienophile may be under the ring (*endo addition*), or it may be the smaller side (*exo addition*):



Most of the time, the addition is predominantly endo; that is, the more bulky side of the alkene is under the ring, and this is probably true for open-chain dienes also.[2049] However, exceptions are known, and in many cases mixtures of exo and endo addition products are found.[2050] An imidazolidone catalyst was used to give a 1:1.3 mixture favoring the exo isomer in a reaction of conjugated aldehydes and cyclopentadiene.[2051] It has been argued that facial selectivity is not due to torsional angle decompression.[2052] Secondary orbital interactions.[2053] have been invoked, but this approach has been called into question.[2054] There has been a direct evaluation of such interactions, however.[2055] The endo/exo ratio can be influenced by the nature of the solvent.[2056]

5. As we have seen, the Diels–Alder reaction can be both stereoselective and regioselective.[2057] In some cases, the Diels–Alder reaction can be made enantioselective[2058] Solvent effects are important in such reactions.[2059] The role of reactant polarity on the course of the reaction has been examined.[2060] Most enantioselective Diels–Alder reactions have used a chiral dienophile (e.g., **199**) and an achiral diene,[2061] along with a Lewis acid catalyst (see below). In such cases, addition of the diene to the two faces[2062] of **199** takes place at different rates, and **200** and **201** are formed in different amounts.[2063] An achiral compound A can be converted to a chiral compound by a chemical reaction with a compound B that is enantiopure. After the reaction, the resulting diastereomers can be separated, providing enantiopure compounds, each with a bond between molecule A and chiral compound B (a chiral auxiliary). Common chiral auxiliaries include chiral carboxylic acids, alcohols, or sultams. In the case illustrated, hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric Diels–Alder reactions have also been carried out with achiral dienes and dienophiles, but with an optically active catalyst.[2064] Many chiral catalysts

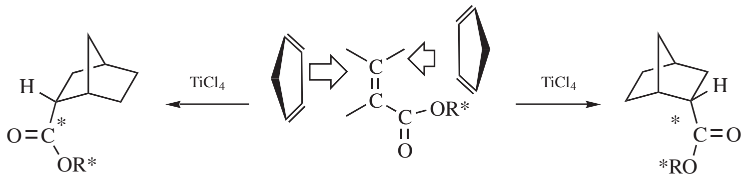
have been developed.[2065] In many cases, asymmetric Lewis acids form a chiral complex with the dienophile.[2066]



200 199 201

R = (+) or (–) phenylmenthyl

Many interesting compounds can be prepared by the Diels–Alder reaction,[2067] some of which would be hard to make in any other way. Azelines react with dienes to form cyclohexene derivatives fused to a four-membered ring amine (azetidine).[2068] The C_{60}-Fullerenes undergo Diels–Alder reactions,[2069] and the reaction is reversible.[2070] Bicyclic sultams can be prepared by an intramolecular Diels–Alder reaction.[2071] Polycyclic lactones can be prepared.[2072]Aromatic compounds can behave as dienes,[2073] but benzene is very unreactive toward dienophiles,[2074] and very few dienophiles (one of them is benzyne) have been reported to give Diels–Alder adducts with it.[2075] Naphthalene and phenanthrene are also quite resistant, although naphthalene has given Diels–Alder addition at high pressures.[2076] However, anthracene and other compounds with at least three linear benzene rings give Diels–Alder reactions readily. The interesting compound triptycene can be prepared by a Diels–Alder

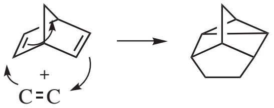
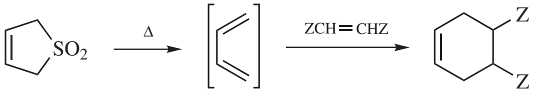
reaction between benzyne and anthracene:[2077] For both all-carbon and hetero systems, the "diene" can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, for example,[2078]



This last reaction is known as the *homo–Diels–Alder reaction*. A similar reaction has been reported with alkynes, using a mixture of a cobalt complex, ZnI_2 and tetrabutylammonium borohydride as catalysts.[2079]

Competing reactions are polymerization of the diene or dienophile, or both, and [1,2]-cycloaddition (**15-63**). Intramolecular versions of the Diels–Alder reaction are well-known, and this is a powerful method for the synthesis of mono- and polycyclic compounds.[2080] There are many examples and variations. Internal Diels–Alder reactions can be viewed as linking the diene and alkene by a tether, usually of carbon atoms. If the tether is replaced by functional groups that allow the selectivity inherent to the intramolecular cycloaddition, but can be cleaved afterward, a powerful modification is available. Indeed, such tethered cycloaddition reactions are increasingly common. After cycloaddition, the tether can be cleaved to give a functionalized cyclohexene derivative. Such tethered reactions allow enhancement of stereoselectivity[2081] and sometimes reactivity, relative to an untethered reaction, giving an indirect method for enhancing those parameters. Tethers or linkages include C—O—SiR_2—C[2082] or a C—O—SiR_2—O—C,[2083] or hydroxamides.[2084] Transient tethers can be used, as in the reaction of a diene having an allylic alcohol unit in a reaction is allyl alcohol, with $AlMe_3$, to give the cycloadduct with good selectivity.[2085]



3-Sulfolene

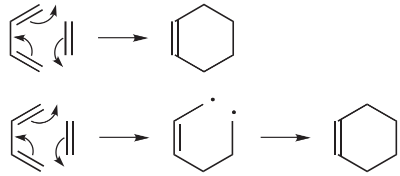
The Diels–Alder reaction is usually reversible, although the retro reaction typically occurs at significantly higher temperatures than the forward reaction. However, the reversibility of the reaction and has been used to protect double bonds.[2086] A convenient substitute for butadiene in the Diels–Alder reaction is the compound 3-sulfolene since the latter is a solid which is easy to handle while the former is gas.[2087] Butadiene is generated *in situ* by a reverse Diels–Alder reaction (see **17-20**).

Mechanism *a*

Mechanism *b*



There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed Diels-Alder reaction.[2088] In mechanism *a* there is a cyclic six-centered transition state and no intermediate. The reaction is concerted and occurs in one step. In mechanism *b*, one end of the diene fastens to one end of the dienophile first to give a diradical, and then, in a second step, the other ends become fastened.[2089] A diradical formed in this manner must be a singlet; that is, the two unpaired electrons must have opposite spins, by an argument similar to that outlined on p. 277. The third mechanism (*c*, not shown) is similar to mechanism *b*, but the initial bond and the subsequent bond are formed by movements of electron pairs and the intermediate is a diion. There have been many mechanistic investigations of the Diels–Alder reaction. The bulk of the evidence suggests that most Diels–Alder reactions take place by the one-step cyclic mechanism *a*,[2090] although it is possible

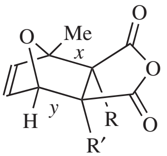
that a diradical[2091] or even a diion[2092] mechanism may be taking place in some cases. Radical cation Diels–Alder reactions have been considered.[2093] The main evidence in support of mechanism *a* is as follows: (*1*) The reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration. (*2*) In general, the rates of Diels–Alder reactions depend very little on the nature of the solvent. This would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state. (*3*) It was shown that, in the decomposition of **202**, the isotope effect k_I/k_{II} was equal to 1.00 within experimental error.[2094] If bond *x* were to break before bond *y*, there



I: R = H, R′ = D

II: R = D, R′ = H

202

should surely be a secondary isotope effect. This result strongly indicates that the bond breaking of *x* and *y* is simultaneous. This is the reverse of a Diels–Alder reaction, and by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds *x* and *y*. Subsequently, a similar experiment was carried out on the forward reaction[2095] and the result was the same. There is also other evidence for mechanism *a*.[2096] However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous.[2097] In the transition state of a synchronous reaction both new σ bonds would be formed to the same extent, but a Diels–Alder reaction with non-symmetrical components might very well be non-synchronous;[2098] that is, it could have a transition state in which one

bond has been formed to a greater degree than the other.[2099] A biradical mechanism has been proposed for some Diels–Alder reactions.[2100]

In another aspect of the mechanism, the effects of electron-donating and electron-withdrawing substituents (p. 1196) indicate that the diene is behaving as a nucleophile and the dienophile as an electrophile. However, this can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride and not at all with tetracyanoethylene, although the latter is normally the most reactive dienophile known. It is apparent, then, that this diene is the electrophile in its Diels–Alder reactions.[2101] Reactions of this type are said to proceed with *inverse electron demand*.[2102]

We have emphasized that the Diels–Alder reaction generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of alkenes to cyclobutanes (**15-63**) gives very poor results in most cases, except when photochemically induced. Woodward and Hoffmann, and Fukui have shown that these contrasting results can be explained by the *principle of conservation of orbital symmetry*,[2103] which predicts that certain reactions are allowed and others forbidden. The orbital-symmetry rules (also called the Woodward–Hoffmann rules)[2104] apply *only to concerted reactions*, for example, mechanism *a*, and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. There are several ways of applying the orbital-symmetry principle to cycloaddition reactions, three

of which are used more frequently than others.[2105] Of these three, we will discuss two: the frontier-orbital method and the Möbius–Hückel method. The third, called the correlation diagram method,[2106] is less convenient to apply than the other two.

The Frontier Orbital Method[2107]

As applied to cycloaddition reactions the rule is that *reactions are allowed only when all overlaps between the highest occupied molecular orbital* (HOMO) *of one reactant and the lowest unoccupied molecular orbital* (LUMO) *of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe*. We may recall that monoalkenes have two π molecular orbitals (p. 10) and that conjugated dienes have four (p. 38), as shown in Fig. 15.2. A concerted cyclization of two monoalkenes (a [2 + 2]-reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Fig. 15.3). On the other hand, the Diels–Alder reaction (a [4 + 2]-reaction) is allowed, whether considered from either direction (Fig. 15.4).

These considerations are reversed when the ring closures are photochemically induced since in such cases an electron is promoted to a vacant orbital before the reaction occurs. Obviously, the [2 + 2] reaction is now allowed (Fig. 15.5) and the [4 + 2]-reaction disallowed. The reverse reactions follow the same rules, by the principle of microscopic reversibility. In fact, Diels–Alder adducts are usually cleaved quite readily, while cyclobutanes, despite the additional strain, require more strenuous conditions.

The Möbius–Hückel Method[2108]

In this method, the orbital symmetry rules are related to the Hückel aromaticity rule discussed in Chapter 2.[2109] Hückel's rule, which states that a cyclic system of electrons is aromatic (hence, stable) when it consists of $4n + 2$ electrons, applies of course to molecules in their ground states. In applying the orbital symmetry principle we are not concerned with ground states, but with transition states. In the present method, we do not examine the molecular orbitals themselves, but rather the *p* orbitals before they overlap to form the molecular orbitals. Such a set of *p* orbitals is called a *basis set* (Fig. 15.6). In investigating the possibility of a concerted reaction, we put the basis sets into the position they would occupy in the transition state. Figure 15.7 shows this for both the [2 + 2] and the [4 + 2] ring closures. What we look for are *sign inversions*. In Fig. 15.7, we can see that there are no sign inversions in either case. That is, the dashed line connects only lobes with a minus sign. Systems with *zero or an even number* of sign inversions are called *Hückel systems*. Because they have no sign inversions, both of these systems are Hückel systems. Systems with *an odd number* of sign

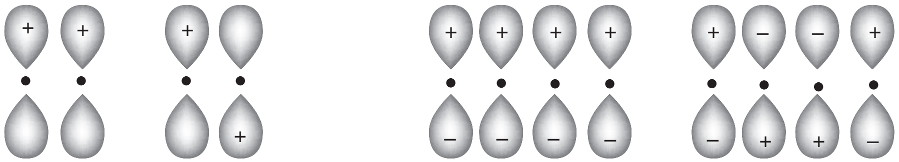

Fig. 15.6. Some basis sets.

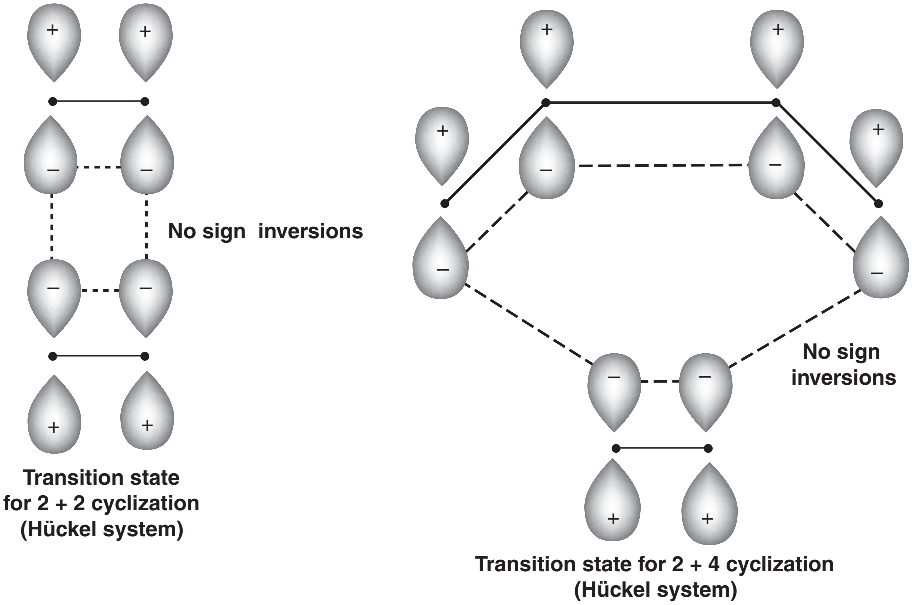

Fig. 15.7. Transition states illustrating Hückel–Möbius rules for cycloaddition reactions.

inversions are called *Möbius systems* (because of the similarity to the Möbius strip, which is a mathematical surface, shown in Fig. 15.8). Möbius systems do not enter into either of these reactions, but an example of such a system is shown on p. $$$.

The rule may then be stated: *A thermal pericyclic reaction involving a Hückel system is allowed only if the total number of electrons is* $4n + 2$. *A thermal pericyclic reaction involving a Möbius system is allowed only if the total number of electrons is* $4n$. For photochemical reactions these rules are reversed. Since both the [4 + 2]- and [2 + 2]-cycloadditions are Hückel systems, the Möbius–Hückel method predicts that the [4 + 2]-reaction, with 6 electrons, is thermally allowed,

Fig. 15.8. A Möbius strip. Such a strip is easily constructed by twisting a thin strip of paper 180° and fastening the ends together.

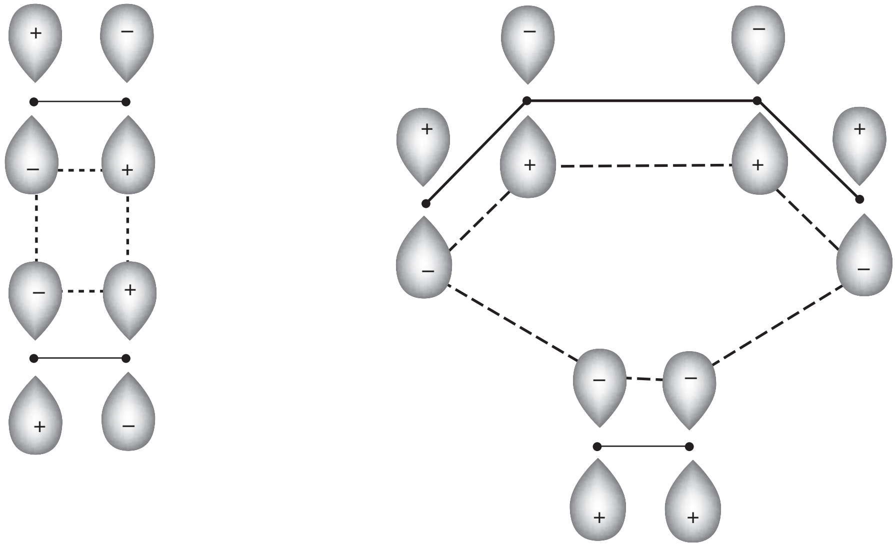

Fig. 15.9. Transition states of [2 + 2]- and [4 + 2]-cyclizations involing other basis sets.

but the [2 + 2]-reaction is not. One the other hand, the [2 + 2]-reaction is allowed photochemically, while the [4 + 2]-reaction is forbidden.

Note that both the [2 + 2] and [4 + 2] transition states are Hückel systems no matter what basis sets we chose. For example, Fig. 15.9 shows other basis sets we might have chosen. In every case there will be zero or an even number of sign inversions.

Thus, the frontier orbital and Hückel–Möbius methods (and the correlation-diagram method as well) lead to the same conclusions: thermal [4 + 2]-cycloadditions and photochemical [2 + 2]-cycloadditions (and the reverse ring openings) are allowed, while photochemical [4 + 2] and thermal [2 + 2] ring closings (and openings) are forbidden.

Application of the same procedures to other ring closures shows that [4 + 4] and [2 + 6] ring closures and openings require photochemical induction while the [4 + 6]- and [2 + 8]-reactions can take place only thermally (see **15-53**). In general, cycloaddition reactions allowed thermally are those with $4n + 2$ electrons, while those allowed photochemically have $4n$ electrons.

It must be emphasized once again that the rules apply only to cycloaddition reactions that take place by cyclic mechanisms, that is, where two σ bonds are formed (or broken) at about the same time.[2110] The rule does not apply to cases where one bond is clearly formed (or broken) before the other. It must further be emphasized that the fact that the thermal Diels–Alder reaction (mechanism *a*) is allowed by the principle of conservation of orbital symmetry does not constitute

[2110]For a discussion of concertedness in these reactions see Lehr, R.E.; Marchand, A.P., in Marchand, A.P.; Lehr, R.E. *Pericyclic Reactions*, Vol. 1, Academic Press, NY, ***1977***, pp. 1–51.

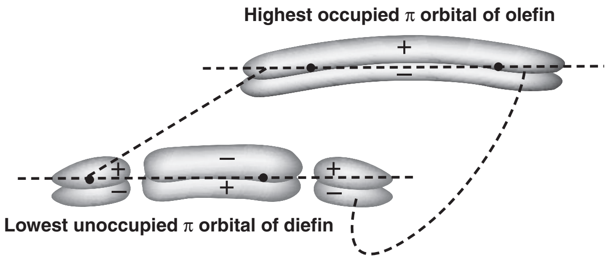

Fig. 15.10. Overlap of orbitals in an antarafacial thermal [4 + 2]-cycloaddition.

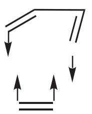
proof that any given Diels–Alder reaction proceeds by this mechanism. The principle merely says the mechanism is allowed, not that it must go by this pathway. However, the principle does say that thermal [2 + 2]-cycloadditions in which the molecules assume a face-to-face geometry cannot[2111] take place by a cyclic mechanism because their activation energies would be too high (however, see below). As we will see (**15-62**), such reactions largely occur by two-step mechanisms. Similarly, [4 + 2]-photochemical cycloadditions are also known, but the fact that they are not stereospecific indicates that they also take place by the two-step diradical mechanism (mechanism *b*).[2112]

In all of the above discussion we have assumed that a given molecule forms both the new σ bonds from the same face of the π system. This manner of bond formation, called *suprafacial*, is certainly most reasonable and almost always takes place. The subscript s is used to designate this geometry, and a normal Diels–Alder reaction would be called a $[_{\pi}2_s + {}_{\pi}4_s]$-cycloaddition (the subscript π indicates that π electrons are involved in the cycloaddition). However, we can conceive of another approach in which the newly forming bonds of the diene lie on *opposite* faces of the π system, that is, they point in opposite directions. This type of orientation of the newly formed bonds is called *antarafacial*, and the reaction would be a $[_{\pi}2_s + {}_{\pi}4_a]$-cycloaddition (a stands for antarafacial). We can easily show by the frontier-orbital method that this reaction (and consequently the reverse ring-opening reactions) are thermally forbidden and photochemically allowed. Thus in order for a $[_{\pi}2_s + {}_{\pi}4_a]$-reaction to proceed, overlap between the highest occupied π orbital of the alkene and the lowest unoccupied π orbital of the diene would have to occur as shown in Fig. 15.10, with a + lobe

[2111]The possibility has been raised that some disallowed reactions may nevertheless proceed by concerted mechanisms: see Schmidt, W. *Helv. Chim. Acta* ***1971***, *54*, 862; *Tetrahedron Lett.* ***1972***, 581; Muszkat, K.A.; Schmidt, W. *Helv. Chim. Acta* ***1971***, *54*, 1195; Baldwin, J.E.; Andrist, A.H.; Pinschmidt Jr., R.K. *Acc. Chem. Res.* ***1972***, *5*, 402; Berson, J.A. *Acc. Chem. Res.* ***1972***, *5*, 406; Baldwin, J.E., in Marchand, A.P.; Lehr, R.E. *Pericyclic Reactions*, Vol. 2, Academic Press, NY, ***1977***, pp. 273–302.

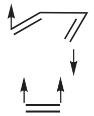
[2112]For example, see Sieber, W.; Heimgartner, H.; Hansen, H.; Schmid, H. *Helv. Chim. Acta* ***1972***, *55*, 3005. For discussions see Bartlett, P.D.; Helgeson, R.; Wersel, O.A. *Pure Appl. Chem.* ***1968***, *16*, 187; Seeley, D.A. *J. Am. Chem. Soc.* ***1972***, *94*, 4378; Kaupp, G. *Angew. Chem. Int. Ed.* ***1972***, *11*, 313, 718.

overlapping a – lobe. Since like signs are no longer overlapping, the thermal reaction is now forbidden. Similarly, thermal [$_{\pi}4_s + _{\pi}2_a$]- and



Normal Diels–Adler reaction

[$4_s + 2_s$]



Twisted Diels–Adler reaction

[$4_a + 2_s$]

[$_{\pi}2_a + _{\pi}2_a$]-cyclizations are forbidden, while thermal [$_{\pi}4_a + _{\pi}2_a$]- and [$_{\pi}2_s + _{\pi}2_a$]-cyclizations are allowed, and these considerations are reversed for the corresponding photochemical processes. Of course, an antarafacial approach is highly unlikely in a [4 + 2]-cyclization,[2113] but larger ring closures could take place by such a pathway, and [2 + 2]-thermal cyclizations, where the [$_{\pi}2_s + _{\pi}2_s$] pathway is forbidden, can also do so in certain cases (see **15-63**). We therefore see that whether a given cycloaddition is allowed or forbidden depends on the geometry of approach of the two molecules involved.

Symmetry considerations have also been advanced to explain predominant endo addition.[2114] In the case of [4 + 2] addition of butadiene to itself, the approach can be exo or endo. It can be seen (Fig. 15.11) that whether the HOMO of the diene overlaps with the LUMO of the alkene or vice versa, the endo orientation is stabilized by additional secondary overlap of orbitals[2115] of like sign (dashed lines between heavy dots). Addition from the exo direction has no such stabilization. Evidence for secondary orbital overlap as the cause of predominant endo orientation, at least in some cases, is that [4 + 6]-cycloaddition is predicted by similar considerations to proceed with predominant exo orientation, and that is what is found.[2116] However, this explanation does not account for endo orientation in cases where the dienophile does not possess additional π orbitals, and a number of alternative explanations have been offered.[2117]

[2113]A possible photochemical [$_{\pi}2a + _{\pi}4_s$]-cycloaddition has been reported: Hart, H.; Miyashi, T.; Buchanan, D.N.; Sasson, S. *J. Am. Chem. Soc.* ***1974***, *96*, 4857.

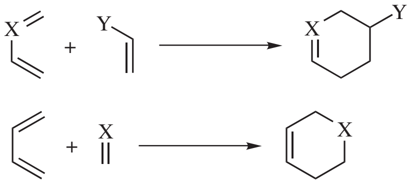
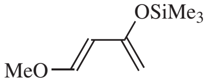
15-61 Heteroatom Diels–Alder Reactions



Carbon–carbon multiple bonds are not the only units that can participate in Diels–Alder reactions. Other double- and triple-bond compounds can be dienophiles and they give rise to heterocyclic compounds.[2118] Among these are N≡C—, —N=C—,[2119] iminium salts,[2120] —N=N—, O=N—,[2121] and —C=O compounds[2122] and even molecular oxygen (**15-62**). It is noted that in the presence of a $YbCl_3$ catalyst, azirines reaction with dienes to give a 1-azabicyclo[4.1.0] heptene.[2123] Several catalysts can be used, depending on the nature of the heteroatoms incorporated into the alkene or diene.[2124] Intramolecular cycloaddition with a diene–imine substrate leads to pyrrolidines.[2125]



203

Aldehydes react with suitably functionalized dienes, such as **203**, known as *Danishefsky's diene*,[2126] and the reaction usually requires a Lewis acid catalyst

such as lanthanide compounds. Aldehydes react using a chiral titanium[2127] or a zirconium[2128] catalyst to give the dihydropyran with good enantioselectivity. Note that the reaction of Danishefsky's diene with an imine, formed *in situ* by reaction of an aryl aldehyde and an aniline derivative, proceeds without a Lewis acid.[2129] Such reactions of aldehydes can be catalyzed with Lewis acids and transition-metal catalysts. The Diels–Alder reaction of aldehydes with dienes can be catalyzed by many transition-metal compounds, including cobalt[2130] and indium[2131] catalyst. Ketones also react with suitably functionalized dienes.[2132]

Azadienes undergo Diels–Alder reactions to form pyridine, dihydro- and tetrahydropyridine derivatives.[2133] Aza-Diels–Alder reactions have been done in ionic liquids.[2134] Similarly, acyl iminium salts C=N(R)—C=O react with alkenes via cycloaddition.[2135] *N*-Vinyl lactim ethers undergo Diels–Alder reactions with a limited set of dienophiles.[2136] Thioketones react with dienes to give Diels–Alder cycloadducts.[2137] The carbonyl group of lactams have also been shown to be a dienophile.[2138] Certain heterocyclic aromatic rings (among them furans)[2139] can also behave as dienes in the Diels–Alder reaction. Some hetero dienes that give the reaction are —C=C—C=O, O=C—C=O, and N=C—C=N.[1999] Nitroso compounds of the type *t*-BuO_2C—N=O react with dienes to give the corresponding 2-azadihydropyran.[2140]

Catalysts, such as $Fe(BuEtCHCO_2)_3$, have been developed that are effective for the heteroatom Diels–Alder reaction.[2141] Indium trichloride ($InCl_3$) is a good catalyst for imino-Diels–Alder reactions.[2142] Hetero-Diels–Alder reactions involving carbonyls have been done in water.[2143] Ultrasound has been used to promote the Diels–Alder reactions of 1-azadienes.[2144] Polymer-supported dienes have been used.[2145]

Hetero- Diels–Alder reactions that proceed with good to excellent asymmetric induction are well known.[2146] Chiral 1-aza-dienes have been developed as substrates, for example.[2147] Chiral catalysts have been developed.[2148] Conjugated aldehydes react with vinyl ethers, with a chiral chromium catalyst, in an inverse electron demand cycloaddition that give a dihydropyran with good enantioselectivity.[2149] Vinyl sulfilimines have been used in chiral Diels–Alder reactions.[2150]

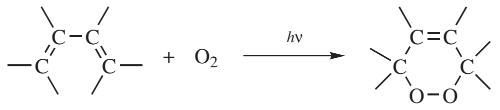
15-62 Photooxidation of Dienes (Addition of Oxygen, Oxygen)

[4 + 2] *OC*,*OC-cyclo*-Peroxy-1/4/addition



204

Conjugated dienes react with oxygen under the influence of light to give cyclic peroxides **204**.[2151] The reaction has mostly[2152] been applied to cyclic dienes.[2153] Cycloaddition of furan has been reported using singlet oxygen.[2154] The scope extends to certain aromatic compounds such as phenanthrene.[2155] Besides those dienes and aromatic rings that can be photooxidized directly, there is a larger group that give the reaction in the presence of a photosensitizer such as eosin (see p. 340).

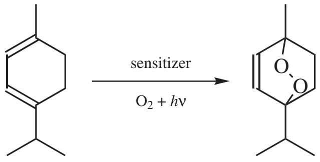
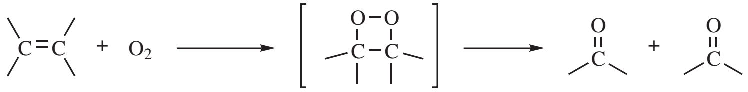
Among these is α-terpinene, which is converted to ascaridole:



As in **14-7**, it is not the ground-state oxygen (the triplet), that reacts, but the excited singlet state,[2156,2157] so the reaction is actually a Diels–Alder reaction (see **15-60**) with singlet oxygen as dienophile:[2158]

Like **15-60**, this reaction is reversible.

We have previously discussed the reaction of singlet oxygen with double-bond compounds to give



205

hydroperoxides (**14-7**), but singlet oxygen can also react with double bonds in another way to give a dioxetane intermediate[2159] (**205**), which usually cleaves to

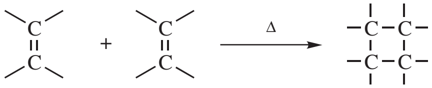
aldehydes or ketones,[2160] but has been isolated.[2161] Both the six-membered cyclic peroxides[2162] and the four-membered **205**[2163] have been formed from oxygenation reactions that do not involve singlet oxygen. If cyclic peroxides, such as **205**, are desired, better reagents[2164] are triphenyl phosphite ozonide $(PhO)_3PO_3$ and triethylsilyl hydrotrioxide ($Et_3SiOOOH$), but yields are not high.[2165]

15-63 [2 + 2]-Cycloadditions

[2 + 2]*cyclo*-Ethylene-1/2/addition



The thermal reaction between two molecules of alkene to give cyclobutane derivatives (a [2 + 2]-cycloaddition) can be carried out where the alkenes are the same or different, but the reaction is not a general one for alkenes.[2166] The cycloaddition can be catalyzed by certain transition-metal complexes.[2167] Dimerization of like alkenes occurs with the following compounds: $F_2C{=}CX_2$ ($X = F$ or Cl) and certain other

fluorinated alkenes (although not $F_2C{=}CH_2$), allenes (to give derivatives of **206**),[2168] benzynes (to give biphenylene derivatives),[2169] activated alkenes (e.g., styrene, acrylonitrile, butadiene), and certain methylenecyclopropanes.[2170] Dimerization of allenes lead to bis(alkylidene) cyclobutanes.[2171] Substituted ketenes can dimerize to give cyclobutenone derivatives, although ketene itself dimerizes in a different manner, to give an unsaturated β-lactone (**16-95**).[2172] Alkenes react with activated alkynes, with a ruthenium catalyst, to give cyclobutenes.[2173]

Intramolecular [2 + 2]-cycloadditions are common in which a diene is converted to a bicyclic compound with a four-membered ring fused to another ring. Heating *N*-vinyl imines, where the vinyl moiety is a silyl enol, gives β-lactams.[2174] Apart from photochemical initiation of such reactions, intramolecular cycloaddition of two conjugated ketone units, in the presence of $PhMeSiH_2$ and catalyzed by cobalt compounds, leads to the bicyclic compound with two ketone substituents.[2175] In a variation of this reaction, a diyne was treated with $Ti(O\textit{i}Pr)_4$/2 *i*-PrMgCl to generate a bicyclic cyclobutene with two vinylidene units.[2176]

Ketenes react with many alkenes to give cyclobutanone derivatives[2177] and intermolecular cycloadditions are well known.[2178] typical reaction is that of dimethylketene and ethene to give 2,2-dimethylcyclobutanone.[2179] Ketenes react with imines via [2 + 2]-cycloaddition to produce β-lactams.[2180] Cycloaddition of an imine with a conjugated ester in the presence of Et_2MeSiH and an iridium

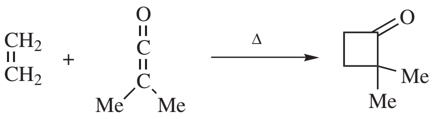
catalyst also gives a β-lactam.[2181]



Different alkenes combine as follows:

1. $F_2C{=}CX_2$ (X = F or Cl), especially $F_2C{=}CF_2$, form cyclobutanes with many alkenes. Compounds of this type even react with conjugated dienes to give four-membered rings rather than undergoing normal Diels–Alder reactions.[2182]
2. Allenes[2183] and ketenes[2184] react with activated alkenes and alkynes. Ketenes give 1,2-addition, even with conjugated dienes.[2185] Ketenes also add to unactivated alkenes if sufficiently long reaction times are used.[2186] Allenes and ketenes also add to each other.[2187]
3. Enamines[2188] form four-membered rings with Michael-type alkenes[2189] and ketenes.[2190] In both cases, only enamines from aldehydes give stable

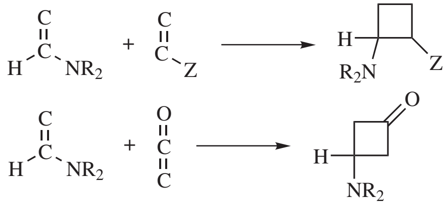
four-membered rings:



The reaction of enamines with ketenes can be conveniently carried out by generating the ketene *in situ* from an acyl halide and a tertiary amine.

4. Alkenes with electron-withdrawing groups may form cyclobutanes with alkenes containing electron-donating groups. The enamine reactions, mentioned above, are examples of this, but it has also been accomplished with tetracyanoethylene and similar molecules, which give substituted cyclobutanes when treated with alkenes of the form C=C—A, where A may be OR,[2191] SR (enol and thioenol ethers),[2192] cyclopropyl,[2193] or certain aryl groups.[2194]

Solvents are not necessary for [2 + 2]-cycloadditions. They are usually carried out at 100–225°C under pressure, although the reactions in Group 4 (IVB) occur under milder conditions.

It has been found that certain [2 + 2]-cycloadditions, which do not occur thermally can be made to take place without photochemical initiation by the use of certain catalysts, usually transition-metal compounds.[2195] Photochemical[2196] [$_\pi 2 + {}_s 2$]-cycloadditions have also been reported. Among the catalysts used are Lewis acids[2197] and phosphine–nickel complexes.[2198] Certain of the reverse cyclobutane ring openings can also be catalytically induced (**18-38**). The role of the catalyst is not certain and may be different in each case. One possibility is that the

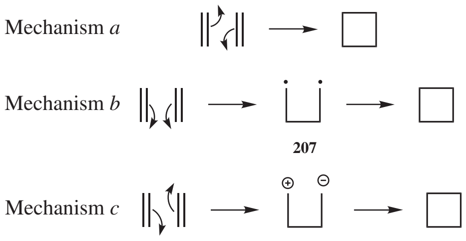
presence of the catalyst causes a forbidden reaction to become allowed, through coordination of the catalyst to the π or s bonds of the substrate.[2199] In such a case, the reaction would of course be a concerted $[2_s + 2_s]$-process. [2200] However, the available evidence is more consistent with nonconcerted mechanisms involving metal–carbon σ-bonded intermediates, at least in most cases.[2201] For example, such an intermediate was isolated in the dimerization of norbornadiene, catalyzed by iridium complexes.[2202]

Thermal cycloadditions leading to four-membered rings can also take place between a cyclopropane ring and an alkene or alkyne[2203] bearing electron-withdrawing groups.[2204] These reactions are $[{}_{\pi}2 + {}_{s}2]$-cycloadditions. Ordinary cyclopropanes do not undergo the reaction, but it has been accomplished with strained systems such as bicyclo[1.1.0]butanes[2205] and bicyclo[2.1.0]pentanes. For example, bicyclo[2.1.0]pentane reacts with maleonitrile (or fumaronitrile) to give all three isomers of 2,3-dicyanonorbornane, as well as four other products.[2206] The lack of stereospecificity and the negligible effect of solvent on the rate indicate a diradical mechanism.

The reaction is similar to the Diels–Alder (in action, not in scope), and if dienes are involved, the latter reaction may compete, although most alkenes react with a diene either entirely by 1,2 or entirely by 1,4 addition. Three mechanisms can be proposed[2207] analogous to those proposed for the Diels–Alder reaction. Mechanism *a* is a



207

208

(a) (b)

Fig. 15.12. Orbital overlap in $[_{\pi}2_s + {}_{\pi}2_s]$-cycloaddition between (*a*) two alkene molecules and (*b*) a ketene and an alkene. S and L stand for small and large

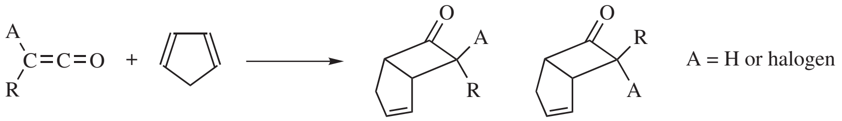
concerted pericyclic process, and mechanisms *b* and *c* are two-step reactions involving, respectively, a diradical (**207**) and a diion (**208**) intermediate. As in **15-60**, a diradical intermediate must be a singlet. In searching for ways to tell which mechanism is operating in a given case, we would expect mechanism *c* to be sensitive to changes in solvent polarity, while mechanisms *a* and *b* should be insensitive. We would also expect mechanism *a* to be stereospecific, while mechanisms *b* and *c* probably would not be stereospecific, although if the second step of these processes takes place very rapidly, before **207** or **208** has a chance to rotate about the newly formed single bond, stereospecificity might be observed. Because of entropy considerations such rapid ring closure might be more likely here than in a [4 + 2]-cycloaddition.

There is evidence that the reactions can take place by all three mechanisms, depending on the structure of the reactants. A thermal $[_{\pi}2_s + {}_{\pi}2_s]$ mechanism is ruled out for most of these substrates by the orbital symmetry rules, but a $[_{\pi}2_s + {}_{\pi}2_a]$ mechanism is allowed (p. 1212), and there is much evidence that ketenes and certain other linear molecules[2208] in which the steric hindrance to such an approach is minimal can and often do react by this mechanism. In a $[_{\pi}2_s + {}_{\pi}2_a]$-cycloaddition the molecules must approach each other in such a way (Fig. 15.12*a*) that the + lobe of the HOMO of one molecule (I) overlaps with both + lobes of the LUMO of the other (II), even although these lobes are on opposite sides of the nodal plane of II. The geometry of this approach requires that the groups S and U of molecule II project *into* the plane of molecule I. This has not been found to happen for ordinary alkenes,[2209] but if

[2208]There is evidence that a cyclopentyne (generated *in situ*) also adds to a double bond by an antarafacial process: Gilbert, J.C.; Baze, M.E. *J. Am. Chem. Soc.* ***1984***, *106*, 1885.

[2209]See, for example, Padwa, A.; Koehn, W.; Masaracchia, J.; Osborn, C.L.; Trecker, D.J. *J. Am. Chem. Soc.* ***1971***, *93*, 3633; Bartlett, P.D.; Cohen, G.M.; Elliott, S.P.; Hummel, K.; Minns, R.A.; Sharts, C.M.; Fukunaga, J.Y. *J. Am. Chem. Soc.* ***1972***, *94*, 2899.

molecule II is a ketene (Fig. 15.12*b*), the group marked U is not present and the $[_{\pi}2_s + _{\pi}2_a]$-reaction can take place. Among the evidence[2210] for this mechanism[2211] is the following: (*1*) The reactions are stereospecific.[2212] (*2*) The isomer that forms is the *more-hindered one*. Thus methylketene plus cyclopentadiene gave only the endo product (**209**, A = H, R = CH_3).[2213] Even more remarkably, when



endo **209** endo **210**

haloalkyl ketenes RXC=C=O were treated with cyclopentadiene, the endo/exo ratio of the product (**209**, **210**, A = halogen) actually *increased* substantially when R was changed from Me to *i*-Pr to *t*-Bu![2214] One would expect preferential formation of the exo products (**210**) from $[_{\pi}2_s + _{\pi}2_s]$-cycloadditions where the molecules approach each other face-to-face, but a $[_{\pi}2_s + _{\pi}2_a]$ process leads to endo products because the ketene molecule (which for steric reasons would approach with its smaller group directed toward the alkene) must twist as shown in Fig. 15.13 (L = larger; S = smaller group) in order for the + lobes to interact and this swings the larger group into the endo position.[2215] The experimental results in which the amount of endo isomer increases with the increasing size of the R group would seem to be contrary to what would be expected from

[2210]For other evidence, see Baldwin, J.E.; Kapecki, J.A. *J. Am. Chem. Soc.* ***1970***, *92*, 4874; Brook, P.R.; Griffiths, J.G. *Chem. Commun.* ***1970***, 1344; Egger, K.W. *Int. J. Chem. Kinet.* ***1973***, *5*, 285; Moon, S.; Kolesar, T.F. *J. Org. Chem.* ***1974***, *39*, 995; Isaacs, N.S.; Hatcher, B.G. *J. Chem. Soc., Chem. Commun.* ***1974***, 593; Hassner, A.; Cory, R.M.; Sartoris, N. *J. Am. Chem. Soc.* ***1976***, *98*, 7698; Gheorghiu, M.D.; Pârvulescu, L.; Drâghici, C.; Elian, M. *Tetrahedron* ***1981***, *37 Suppl.*, 143. See, however, Holder, R.W.; Graf, N.A.; Duesler, E.; Moss, J.C. *J. Am. Chem. Soc.* ***1983***, *105*, 2929.

[2211]On the other hand, molecular-orbital calculations predict that the cycloaddition of ketenes to alkenes does not take place by a $[_{\pi}2_s + _{\pi}2_a]$ mechanism: Wang, X.; Houk, K.N. *J. Am. Chem. Soc.* ***1990***, *112*, 1754; Bernardi, F.; Bottoni, A.; Robb, M.A.; Venturini, A. *J. Am. Chem. Soc.* ***1990***, *112*, 2106; Valentí, E.; Pericàs, M.A.; Moyano, A. *J. Org. Chem.* ***1990***, *55*, 3582.

considerations of steric hindrance (we may call them *masochistic steric effects*), but they are just what is predicted for a $[_{\pi}2_s + {_{\pi}2_a}]$-reaction. (*3*) There is only moderate polar solvent acceleration.[2216] (*4*) The rate of the reaction is not very sensitive to the presence of electron-withdrawing or electron-donating substituents.[2217] Because cycloadditions involving allenes are often stereospecific, it has been suggested that these also take place by the $[_{\pi}2_s + {_{\pi}2_a}]$ mechanism,[2218] but the evidence in these cases is more consistent with the diradical mechanism *b*.[2219]

The diradical mechanism *b* is most prominent in the reactions involving fluorinated alkenes.[2220] These reactions are generally not stereospecific[2221] and are insensitive to solvent effects. Further evidence that a diion is not involved is that head-to-head coupling is found when an unsymmetrical molecule is dimerized. Thus dimerization of $F_2C{=}CFCl$ gives **211**, not **212**. If one pair of electrons moved before the other, the positive end of one molecule would be expected to attack the

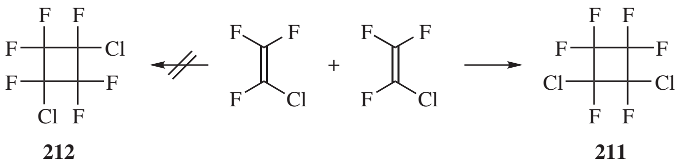
Chem.* ***1990***, *55*, 711; Becker, D.; Denekamp, C.; Haddad, N. *Tetrahedron Lett.* ***1992***, *33*, 827.

[2220]It has been argued that the mechanism here is not the diradical mechanism, but the $[_{\pi}2_s + {_{\pi}2_a}]$ mechanism: Roberts, D.W. *Tetrahedron* ***1985***, *41*, 5529.

[2221]Bartlett, P.D.; Hummel, K.; Elliott, S.P.; Minns, R.A. *J. Am. Chem. Soc.* ***1972***, *94*, 2898.

negative end of the other.[2222]



The diion mechanism[2223] *c* has been reported for at least some of the reactions[2224] in categories 3 and 4,[2225] as well as some ketene dimerizations.[2226] For example, the rate of the reaction between 1,2-bis(trifluoromethyl)-1,2-dicyanoethene and ethyl vinyl ether was strongly influenced by changes in solvent polarity.[2227] Some of these reactions are nonstereospecific, but others are stereospecific.[2228] As previously indicated, it is likely that in the latter cases the diionic intermediate closes before rotation can take place. Such rapid ring closure is more likely for a diion than for a diradical because of the attraction between the opposite charges. Other evidence for the diion mechanism in these cases is that reaction rates are greatly dependent on the presence of electron-donating and electron-withdrawing groups and that it is possible to trap the diionic intermediates.

Whether a given alkene reacts by the diradical or diion mechanism depends, among other things, on the groups attached to it. For example, phenyl and vinyl groups at the α positions of **207** or **208** help to stabilize a diradical, while donors, such as oxygen and nitrogen, favor a diion (they stabilize the positively charged end).[2229] A table on p. 451 of Ref. 2230 shows which mechanism is more likely for [2 + 2]-cycloadditions of various pairs of alkenes.

Thermal cleavage of cyclobutanes[2230] to give two alkene molecules (*cycloreversion*,[2231] the reverse of [2 + 2]-cycloaddition) operates by the diradical mechanism,

and the $[_{\sigma}2_s + _{\sigma}2_a]$ pathway has not been found[2232] (the subscripts σ indicate that σ bonds are involved in this reaction).

In some cases, double bonds add to triple bonds to give cyclobutenes, apparently at about the same rate that they add to double bonds. The addition of triple bonds to triple bonds would give cyclobutadienes, and this has not been observed, except where these rearrange before they can be isolated (see **15-65**)[2233] or in the presence of a suitable coordination compound, so that the cyclobutadiene is produced in the form of a complex (p. 76).[2234]

Although thermal [2 + 2]-cycloaddition reactions are essentially limited to the cases described above, many (although by no means all) double-bond compounds undergo such reactions *when photochemically excited* (either directly or by a photosensitizer, see p. 340), even if they are not in the above categories.[2235] Simple alkenes absorb in the far UV (p. 332), which is difficult to reach experimentally, although this problem can sometimes be overcome by the use of suitable photosensitizers. The reaction has been applied to simple alkenes[2236] (especially to strained compounds, such as cyclopropenes and cyclobutenes), but more often the double-bond compounds involved are conjugated dienes,[2237] α,β-unsaturated ketones,[2238]

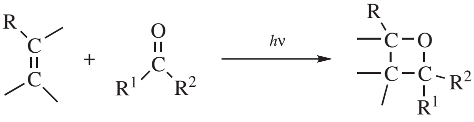
obtained instead of the desired product.



213

The photochemical cycloaddition of a carbonyl, generally from an aldehyde or ketone, and an alkene is called the *Paternò–Büchi reaction*.[2244] This [2 + 2]-cycloaddition gives an oxetane (**213**) and the reaction is believed to proceed via a diradical intermediate. Silyl enol ethers react with aldehydes under nonphotochemical conditions using $ZnCl_2$ at 25°C or $SnCl_4$ at −78°C.[2245]

It is possible that some of these photochemical cycloadditions take place by a $[_{\pi}2_s + _{\pi}2_s]$ mechanism (which is of course allowed by orbital symmetry); when and if they do, one of the molecules must be in the excited singlet state (S_1) and the other in the ground state.[2246] The nonphotosensitized dimerizations of *cis*- and *trans*-2-butene are stereospecific,[2247] making it likely that the $[_{\pi}2_s + _{\pi}2_s]$ mechanism is operating in these reactions. However, in most cases it is a triplet excited state that reacts with the ground-state molecule; in these cases the diradical (or in certain cases, the diionic) mechanism is taking place.[2248] In one intramolecular case, the intermediate diradical has been trapped.[2249] Photosensitized [2π + 2π]-cycloadditions almost always involve the triplet state, and hence a diradical (or diionic) mechanism.

The photochemical diradical mechanism is not quite the same as the thermal diradical mechanism. In the thermal mechanism the initially formed diradical must be a singlet, but in the photochemical process a triplet excited state is adding to a ground state (which is of course a singlet). Thus, in order to conserve spin,[2250] the initially formed diradical must be a triplet; that is, the two electrons must have the same spin. Consequently, the second, or ring-closing, step of the mechanism cannot take place at once, because a new bond cannot form from a combination of two electrons with the same spin, and the diradical has a reasonably long lifetime before collisions with molecules in the environment allow a spin inversion to take

[2250]This is an example of the Wigner spin conservation rule (p. 340). Note that spin conservation is something entirely different from symmetry conservation.

place and the diradical to cyclize. We would therefore predict nonstereospecificity, and that is what is found.[2251] It has been believed that at least some [2 + 2]-photocycloadditions take place by way of exciplex intermediates[2252] [an *exciplex*[2253] is an excited EDA complex (p. 342) that is dissociated in the ground state; in this case one double bond is the donor and the other the acceptor], but there is evidence against this.[2254]

In **15-60**, we used the principle of conservation of orbital symmetry to explain why certain reactions take place readily and others do not. The orbital-symmetry principle can also explain why certain molecules are stable although highly strained. For example, quadricyclane and hexamethylprismane[2255] are thermodynamically much less stable (because much more strained) than their corresponding isomeric dienes, norbornadiene and

214

Quadricyclane Norbornadiene Hexamethylprismane (A Dewar benzene)

hexamethylbicyclo[2.2.0]hexadiene (**214**).[2256] Yet the former two compounds can be kept indefinitely at room temperature, although in the absence of orbital-symmetry considerations it is not easy to understand why the electrons simply do not move over to give the more stable diene isomers. The reason is that both these reactions involve the conversion of a cyclobutane ring to a pair of double bonds (a $_s2 + {}_s2$ process) and, as we have seen, a thermal process of this sort is forbidden by the Woodward–Hoffmann rules. The process is allowed photochemically, and we are not surprised to find that both quadricyclane and hexamethylprismane are photochemically converted to the respective dienes at room temperature or below.[2257] It is also possible to conceive of simple

[2251]See, for example, Liu, R.S.H.; Hammond, G.S. *J. Am. Chem. Soc.* ***1967***, *89*, 4936; Kramer, B.D.; Bartlett, P.D. *J. Am. Chem. Soc.* ***1972***, *94*, 3934.

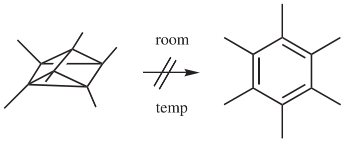
[2255]This compound can be prepared by photolysis of **210**, another example of an intramolecular photochemical [2 + 2]-cycloaddition: Lemal, D.M.; Lokensgard, J.P. *J. Am. Chem. Soc.* ***1966***, *88*, 5934; Schäfer, W.; Criegee, R.; Askani, R.; Grüner, H. *Angew. Chem. Int. Ed.* ***1967***, *6*, 78.

[2256]For a review of this compound, see Schäfer, W.; Hellmann, H. *Angew. Chem. Int. Ed.* ***1967***, *6*, 518.

[2257]These conversions can also be carried out by the use of transition-metal catalysts: Hogeveen, H.; Volger, H.C. *Chem. Commun.* ***1967***, 1133; *J. Am. Chem. Soc.* ***1967***, *89*, 2486; Kaiser, K.L.; Childs, R.F.; Maitlis, P.M. *J. Am. Chem. Soc.* ***1971***, *93*, 1270; Landis, M.E.; Gremaud, D.; Patrick, T.B. *Tetrahedron Lett.* ***1982***, *23*, 375; Maruyama, K.; Tamiaki, H. *Chem. Lett.* ***1987***, 683.

bond rearrangements whereby hexamethylprismane is converted to hexamethylbenzene, which



of course is far more stable than either hexamethylprismane or **214**. It has been calculated that hexamethylbenzene is at least 90 kcal mol^{-1} (380 kJ mol^{-1}) more stable than hexamethylprismane. The fact that hexamethylprismane does not spontaneously undergo this reaction has prompted the observation[2258] that the prismane has "the aspect of an angry tiger unable to break out of a paper cage." However, a correlation diagram for this reaction[2259] discloses that it too is a symmetry-forbidden process. All three of these "forbidden" reactions do take place when the compounds are heated, but the diradical mechanism is likely under these conditions.[2259]

Bicyclo[2.2.0]hexadienes and prismanes are *valence isomers* of benzenes.[2260] These compounds actually have the structures that were proposed for benzenes in the nineteenth century. Prismanes have the Ladenburg formula, and bicyclo[2.2.0]hexadienes have the Dewar formula. Because of this bicyclo[2.2.0]hexadiene is often called Dewar benzene. On p. 32, it was mentioned that Dewar formulas are canonical forms (although not very important) of benzenes. Yet they also exist as separate compounds in which the positions of the nuclei are different from those of benzenes.

Carbenes and substituted carbenes add to double bonds to give cyclopropane derivatives by what can be considered as a formal [1 + 2]-cycloaddition.[2261] Many carbene derivatives, for example, PhCH, ROCH,[2262] $Me_2C{=}C$, $C(CN)_2$, have been added to double bonds, but the reaction is often performed with CH_2 itself, with halo and dihalocarbenes,[2263] and with carbalkoxycarbenes[2264] (generated from diazoacetic esters). Alkylcarbenes HCR have been added to alkenes,[2265] but more often these rearrange to give alkenes (p. 291). The carbene can be generated in any of the ways normally used (p. 287). However, most reactions in which a cyclopropane is formed by treatment of an alkene with a carbene "precursor" do not actually involve free carbene intermediates. In some cases, it is certain that free carbenes are not involved, and in other cases there is doubt. Because of this, the term *carbene transfer* is often used to cover all reactions in which a double bond is converted to a cyclopropane, whether a carbene or a carbenoid (p. 288) is actually involved.

Carbene itself ($:CH_2$) is extremely reactive and gives many side reactions, especially insertion reactions (**12-21**), which greatly reduce yields. This competition is also true with rhodium-catalyzed diazoalkane cyclopropanations[2266] (see below). When it is desired to add $:CH_2$ for preparative purposes, free carbene is not used, but the Simmons–Smith procedure (p. 1241) or some other method that does not involve free carbenes is employed instead. Halocarbenes are less active than carbenes, and this reaction proceeds quite well, since insertion reactions do not interfere.[2267] The absolute rate constant for addition of selected alkoxychlorocarbene to butenes has been measured to range from 330 to $1 \times 10^4 M^{-1}$ s^{-1}.[2268] A few of the many ways[2269] in which halocarbenes or carbenoids are generated for

[2269]Much of the work in this field has been carried out by Seyferth, D. and co-workers; see, for example, Seyferth, D.; Haas, C.K. *J. Org. Chem.* ***1975***, *40*, 1620; Seyferth, D.; Haas, C.K.; Dagani, D. *J. Organomet. Chem.* ***1976***, *104*, 9.

this reaction are the following,[2270] most of which involve formal elimination (the first two steps of the S_N1cB mechanism, p. 521):

$$CH_2Cl_2 + RLi \longrightarrow CHCl$$

$$N_2CHBr \xrightarrow{h\nu} CHBr$$

$$CHCl_3 + {}^{-}OH \longrightarrow CCl_2$$

$$PhHgCCl_2Br \xrightarrow{\Delta} CCl_2 \quad \text{Ref. }^{2271}$$

$$Me_3SnCF_3 + NaI \longrightarrow CF_2 \quad \text{Ref. }^{2272}$$

$$Me_2CBr_2 \xrightarrow{\text{electrolysis}} Me_2C\!: \quad \text{Ref. }^{2273}$$

The reaction between $CHCl_3$ and HO– is often carried out under phase transfer conditions.[2274] It has been shown that the reaction between $PhCHCl_2$ and *t*-BuOK produces a carbenoid, but when the reaction is run in the presence of a crown ether, the free Ph(Cl)C: is formed instead.[2275] The reaction of iodoform and $CrCl_2$ leads to iodocyclopropanes upon reaction with alkenes.[2276] Dihalocyclopropanes are very useful compounds[2277] that can be reduced to cyclopropanes, treated with magnesium or sodium to give allenes (**18-3**), or converted to a number of other products.

Alkenes of all types can be converted to cyclopropane derivatives by this reaction, but difficulty may be encountered with sterically hindered ones.[2278]

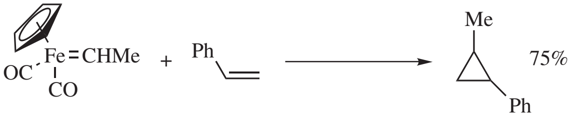
Even tetracyanoethylene, which responds very poorly to electrophilic attack, gives cyclopropane derivatives with carbenes.[2279] Conjugated dienes give 1,2-addition to give a vinylcyclopropane.[2280] Addition of a second mole gives bicyclopropyl derivatives.[2281] 1,4-Addition is rare but has been reported in certain cases.[2282] Carbene adds to ketene to give cyclopropanone.[2283] Allenes react with carbenes to give cyclopropanes with exocyclic unsaturation:[2284]

A second equivalent gives spiropentanes. In fact, any size ring with an exocyclic double bond can be converted by a carbene to a spiro compound.[2285]

Free carbenes can also be avoided by using transition-metal–carbene complexes $L_nM{=}CRR'$ (L = a ligand, M = a metal),[2286] which add the group CRR′ to double bonds.[2287] An example is the reaction of iron carbene **215**.[2288]



215

These complexes can be isolated in some cases; in others they are generated *in situ* from appropriate precursors, of which diazo compounds are among the

most important. Chromium complexes have been used for the cyclopropanation of alkenes.[2289]

Polymer-supported benzenesulfonyl azides have been developed as a safe diazo-transfer reagent.[2290] These compounds, including CH_2N_2 and other diazoalkanes, react with metals or metal salts (copper, palladium,[2291] and rhodium are most commonly used) to give the carbene complexes that add: CRR′ to double bonds.[2292] Diazoketones and diazoesters with alkenes to give the cyclopropane derivative, usually with a transition-metal catalyst, such as a copper complex.[2293] The ruthenium catalyst reaction of diazoesters with an alkyne give a cyclopropene.[2294] An X-ray structure of an osmium catalyst intermediate has been determined.[2295] Electron-rich alkenes react faster than simple alkenes.[2296]

Optically active complexes have been used for enantioselective cyclopropane synthesis.[2297] Decomposition of diazoalkanes in the presence of chiral rhodium[2298] copper,[2299] or ruthenium[2300] complexes leads to optically active cyclopropanes.
